Map Accuracy. A measure of the maximum error allowed in horizontal location and elevation on maps. For example, the USGS map accuracy standards for 1:24,000-scale maps are that 90% of well-defined objects should appear within 40 feet (12.2 meters) of their true location. See United States National Map Accuracy Standards.

Map Attribute. See Attribute.

Map Class. Plant communities and non-vegetated elements that can be discerned on an aerial photograph. If individual plant associations cannot be distinguished on an aerial photograph, map classes lumping related plant associations must be developed. For example, at Devils Tower National Monument there were five associations in the

Ponderosa Pine Woodland Alliance, but it was necessary to create two ponderosa pine map classes because the associations could not be distinguished on the photography. Also known as Map Unit.

Map Code. The map class code number related to the map class. For example, map class Cinder Sparse Mosaic has a map code of 1.

Map Scale. The relationship between a distance portrayed on a map and the same distance on the earth's surface (Dana 1999). A scale of 1 inch = 1000 feet can also be expressed as 1:12,000 (i.e., 1 inch on the map equals 12,000 inches on the earth). When a map is reproduced in a different size, the scale reference (1:12,000) is no longer valid but the scale bar on the map is still valid.

Map Projection. A systematic conversion of locations on the Earth's surface from spherical coordinates to planar coordinates (ESRI 1994).

Map Unit. See Map Class.

Map Validation. The process of field checking photointerpretation. This step is completed prior to accuracy assessment.

Metadata. A text file describing how a spatial database was created. Metadata files document how the data were created, their content, quality, condition, and other characteristics. Metadata's purpose is to help organize and maintain an organization's internal investment in spatial data, provide information about an organization's data holdings to data catalogues, clearing-houses, and brokerages, and provide information to process and interpret data received through a transfer from an external source (FGDC 1997). The FGDC sets the content standards for metadata. The NBII has developed

software to aid in creating metadata and commercial software programs are also available.

Minimum Mapping Unit (MMU). The smallest area that is consistently delineated during photointerpretation. The MMU for the USGS-NPS Vegetation Mapping Program is 0.5 hectares.

Mosaic (Biology). An intermixing of plant associations in an area that has a unique photosignature but is too intricate for individual associations to be delineated. Compare with Complex.

Mosaic (Image). An image composed of an assemblage of edge-matched, overlapping aerial photographs.

National Biological Information Infrastructure (NBII). A broad, collaborative program to provide access to data and information relating to the Nation's biological resources. The NBII links diverse, high-quality biological databases, and analytical tools maintained by NBII partners in government agencies, academic institutions, nongovernmental organizations, and private industries.

National Biological Service (NBS). See Biological Resources Discipline.

National Map Accuracy Standards. See US National Map Accuracy Standards.

National Park Service (NPS). A U.S. Department of Interior agency created in 1916 and charged with preserving the natural and cultural resources of the national park system for the enjoyment, education, and inspiration of this and future generations. NPS manages the National Parks and the Inventory and Monitoring Program and works

closely with USGS to coordinate the USGS-NPS Vegetation Mapping Program.

National Vegetation Classification Standard (NVCS). The Federal Geographic Data Committee's vegetation classification model. It has been adapted to the formation level (as of June 2001); adoption of standards for finer levels is expected in the spring of 2004 with the adoption of the Ecological Society of America's 'Guidelines For Describing Associations and Alliances of the U.S. National Vegetation Classification'. Currently the U.S. National Vegetation Classification (NVC) is maintained by NatureServe and can be examined on their on-line NatureServe Explorer database (<http://www.natureserve.org/explorer/>).

Natural Heritage Programs. Operate throughout much of the western hemisphere gathering, managing, and distributing detailed information about the biological diversity found within their jurisdiction. Most programs are part of government agencies such as fish and wildlife departments, although some are run by universities or nongovernmental organizations.

Natural Resources Conservation Service (NRCS). A USDA agency that is the lead federal agency for conservation on private land and is a partner in land conservation with private land managers, conservation districts; resource conservation and development (RC&D) councils; state and local conservation agencies; state, local, and Tribal governments; rural communities; businesses; and others. The NRCS produces the nation's Soil Survey reports.

Natural Vegetation. Plant life of an area that appears to be substantially unaltered by human activities. Most existing vegetation has been subjected to some human modification, so a clear distinction between natural

and cultural vegetation may sometimes be difficult (Grossman et al. 1998).

NatureServe. A non-profit organization dedicated to developing and providing knowledge about the world's natural diversity. In cooperation with the Natural Heritage Network, NatureServe collects and develops authoritative information about the plants, animals, and ecological communities of the Western Hemisphere. NatureServe maintains databases to support the United States National Vegetation Classification Standard (NVCS) and the relevé data that it is based on. Nature-Serve's role in this project was to help develop the vegetation community classification. Formerly known as ABI (Association for Biodiversity Information).

North American Datum (NAD). The standard cartographic reference for map projections and coordinates throughout North America (see also Datum). Usually associated with a version, such as 1927 or 1983. This project used the 1983 North American datum (NAD83), which is consistent with satellite location systems. The 1983 datum uses the GRS 80 spheroid whereas the 1927 datum uses the Clarke 1866 spheroid (ESRI 1994).

Observation Point. Field data used to support map class and vegetation classification development. These points are collected during reconnaissance and verification field work.

Omission Errors. See Producer's Accuracy.

Order. The 2nd highest level in the NVCS hierarchy (FGDC 1997). An order is generally defined by dominant life form (tree, shrub, dwarf shrub, herbaceous, or non-vascular)

Ortho Image. An aerial photograph that has had the distortions common to aerial photography removed and has been registered to locations on the earth. A digital ortho image can be placed in a GIS and have other layers, such as vegetation, overlain on it. A DOQQ is an ortho image. Also sometimes called an ortho-photo.

Pattern. Describes the distribution of vegetation features across a landscape. Some examples include: Evenly Dispersed, Clumped/Bunched, Gradational/Transitional, or Alternating. Compare with Density and Height.

Photointerpretation. The art and science of identifying and delineating objects and conditions on an aerial photograph.

Photointerpretation Key. A description, often accompanied by pictures of examples, of the visual elements that make up the photographic signature of each map class.

Photointerpretation Modifiers. Codes used to describe special features that are not part of the NVCS. For example, an agency may be interested in eagle nests, beaver dams, prairie dog towns, and forest blow-down areas.

Photosignature. See Signature.

Physiognomic Modifiers. Modifiers used to describe the physiognomic structure of the vegetation found within a mapped polygon (e.g., cover, density, pattern, height).

Physiognomy. The structure and life form of a plant community (FGDC 1997).

Plant Association. See Association.

Plant Community. See Community.

PLANTS database. A database maintained by the Natural Resource Conservation Service. This database focuses on vascular plants, mosses, liverworts, hornworts, and lichens of the U.S. and its territories. The PLANTS Database includes names, checklists, automated tools, identification information, species abstracts, distributional data, crop information, plant symbols, plant growth data, plant materials information, links, references, and other information. This is the database that maintains the current list of accepted scientific names. See <http://plants.usda.gov/>.

Plot. A defined location of a certain size where the data necessary to classify the vegetation is collected. Plots are generally located non-randomly and plot size varies depending on the vegetation being sampled. See: <http://biology.usgs.gov/npsveg/fieldmethods>. Plot data are entered into a database for storage and analysis. Also referred to as Relevés.

Polygon. A multisided figure that represents area on a map. A polygon is defined by the lines that consist of the boundary and the label point within its boundary used for identification. Polygons have attributes that describe the geographic feature they represent.

Positional Accuracy. How close a point in a spatial database is to its actual location on the earth's surface. The National Map Accuracy Standard for horizontal positional accuracy at the 1:24,000 scale is 1/50 of an inch (40 feet/12.2 m) of an object's actual location.

Potential Vegetation. The vegetation that would become established if succession were completed without interference under the present climatic and edaphic conditions. Contrast with Existing Vegetation.

Precision Lightweight GPS Receiver (PLGR). A small handheld, global positioning system (GPS) receiver developed for the military and featuring anti-spoofing and anti-jamming capability.

Producer's Accuracy. The probability that a reference sample (the ground data) has been classified correctly, also known as error of omission. This quantity is computed by dividing the number of samples that have been classified correctly by the total number of reference samples in that class (Storey and Congalton 1986). Compare with User's Accuracy.

Projection. A two-dimensional representation of data located on a curved surface. Projections always involve distortion, so the cartographer must choose which characteristics (distance, direction, scale, area, or shape) will be emphasized at the expense of the other characteristics (Snyder 1982). In this project, all spatial data use the Universal Transverse Mercator (UTM) coordinate system that is based on the transverse mercator projection applied between 84 degrees north and 80 degrees south latitude.

Quadrangle. A USGS 7.5 minute topographic map.

Quarter Quad(rangle). A map or image that includes $\frac{1}{4}$ of a 7.5-minute quadrangle map. Quarter quadrangles are organized in geographic quadrants of the original map: northeast, northwest, southeast, and southwest.

Rectify. To remove distortions from aerial photographs in the process of transferring interpreted photographs into a spatial database. Distortions on photographs are due to topographic relief on the ground, radial distortion in the geometry of the aerial photog-

raphy, tip and tilt of the plane, and differences in elevation of the airplane from its nominal scale. This process may be separate or included in the registration process, depending on the technology used.

Reference Data. The field data that is collected for the accuracy assessment.

Register. The process of relating objects on an aerial photograph to the surface of the earth. This is necessary to be able to place vegetation data in a GIS with other spatial data such as roads, topography, or soils. This process may be separate or may be included in the rectification process, depending on the technology used. See also Transfer.

Relevé. See Plot.

Sample Data. Sample data are the map classes that were photo-delineated as occurring on the vegetation map. The sample data is compared to the reference data (see reference data) to compute map accuracy.

Scale. The relationship between a distance portrayed on a map and the same distance on the Earth (Dana 1999). A map scale can be defined by a fraction (e.g., 1 unit on map / 12,000 units on ground) or by a graphic scale bar.

Signature. The unique combination of color, texture, pattern, height, physiognomy, and position in the landscape used by photointerpreters to identify map classes on an aerial photograph. Or, characteristics of an item on a photograph by which the item may be identified (ASP 1984). Also referred to as Photosignature.

Small-scale. Refers to a map or image with a relatively small-scale denominator (e.g. 1:1,000). Small-scale maps cover a small

area, have fine detail, and the images have high resolution (e.g. 0.5m per pixel).

Spatial. Refers to features or phenomena distributed in geographic space and having physical, measurable dimensions.

Special Modifiers. See Photointerpretation Modifiers.

Stratum. A horizontal layer of vegetation. A stratum may be defined by the life form of the vegetation (tree, shrub, herbaceous), its relative position in the community (understory) or its actual height.

Structure (Vegetation). The spatial distribution pattern of life forms in a plant community, especially with regard to their height, abundance, or coverage within the individual layers. Synonymous with Physiognomy.

Subclass. The level in the NVCS hierarchies based on growth form characteristics (Grossman et al. 1998).

Subgroup. The level in the NVCS hierarchies that divides each group into either a "natural/semi-natural" or "cultural" (planted/cultivated) subgroup (Grossman et al. 1998).

The Nature Conservancy (TNC). A non-profit conservation organization founded in 1951. Working with communities, businesses and people, TNC protects millions of acres of valuable lands and waters worldwide. TNC was the original caretaker of the National Vegetation Classification (NVC), but those responsibilities have been spun off to NatureServe. TNC no longer has an active role with the USGS-NPS Vegetation Mapping Program.

Thematic Accuracy. The correctness of the map classes in relation to the vegetation on the ground. This is determined through standardized accuracy assessment procedures. The program standard is 80% accuracy for each map class within 90% confidence intervals. See Accuracy Assessment, Producer's Accuracy, and User's Accuracy.

Thematic Map. A map that displays the spatial distribution of a single attribute or a specific topic, such as land-cover and land-use classes.

Topology. The explicit definition of how map features represented by points, lines and areas are related. Specifically, accounting for issues of connectivity and adjacency of features.

Topographic Quads. USGS paper maps showing the topography of an area as well as roads, railroads, water bodies, buildings, urban developments, and wetlands. These come in a variety of scales, but commonly refer to 1:24,000-scale 7.5-minute quads. Informally referred to as topo quads.

Transfer. The process of entering data from interpreted aerial photo overlays into a digital database. The data is usually registered and rectified into real-world geographic coordinates. This process varies depending on the type of technology used. See also Transformation.

Transform(ation). The process of converting coordinates (map or image) from one coordinate system to another. This involves scaling, rotation, translation, and warping (images) (ESRI 1994).

Transition Zone. An area where the vegetation composition and structure is intermediate between two associations. The tran-

sition zone may be narrow as associations abruptly change due to a significant change in a major habitat factor, such as a cliff, or it may be broad when the physical environment changes gradually. Transition zones may be challenging to classify or map.

Type. A generic term that can mean any vegetation level in the NVCS, whether an association, alliance, formation, etc, or even a combination of levels. It is a vague but useful term. It is correctly used when the focus is not on a specific unit of vegetation, but rather when used loosely to explain some other point (e.g., "We do not have a good grasp of how vegetation types at Acadia link to the map classes."). Also known as Vegetation Type.

United States Geological Survey (USGS). Established in 1879, the USGS is the natural science agency for the Department of the Interior. The USGS is one of the host agencies, along with the National Park Service, for the USGS-NPS Vegetation Mapping Program.

United States National Map Accuracy Standards. Defines accuracy standards for published maps, including horizontal and vertical accuracy, accuracy testing method, accuracy labeling on published maps, labeling when a map is an enlargement of another map, and basic information for map construction as to latitude and longitude boundaries. The table below shows the standard for some common map scales. Note that the conversion of paper maps into digital data usually creates additional error.

Scale	Engineering Scale	Accuracy Standard
1:1,200	1"=100'	+/- 3.33 feet
1:2,400	1"=200'	+/- 6.67 feet
1:4,800	1"=400'	+/- 13.33 feet
1:9,600	1"=800'	+/- 26.67 feet

1:10,000		+/- 27.78 feet
1:12,000	1"=1000'	+/- 33.33 feet
1:24,000	1"=2000'	+/- 40.00 feet
1:63,360	1"=one mile	+/- 105.60 feet
1:100,000		+/- 166.67 feet

Universal Transverse Mercator (UTM).

A map coordinate system (not a map projection) that is defined by the Transverse Mercator projection which has a set of zones defined by a central meridian as shown in the figure below for the United States (ESRI 1994):

User's Accuracy. In assessing the thematic accuracy of a vegetation map, the probability that a sample from the mapped data actually represents that category on the ground, also known as error of commission. This quantity is computed by dividing the number of correctly classified samples by the total number of samples that were classified as belonging to that category (Story and Congalton 1986). Compare with Producer's Accuracy.

Vector Data. Spatial (usually digital) data that consists of using coordinate pairs (x, y) to represent locations on the earth. Features can take the form of single points, lines, arcs or closed lines (polygons).

Vegetation. The plant cover over an area (FGDC 1997).

Vegetation Characterization. The detailed description of a plant association's diagnostic and dominant species, structure, and/or ecological processes. See: <http://biology.usgs.gov/npsveg/agfo/descript.pdf>

Vegetation Classification. The process of categorizing vegetation into recognizable and consistent elements. Also a document that lists and organizes the vegetation communities in an area. An example of a vegetation classification can be found at <http://biology.usgs.gov/npsveg/agfo/methods.pdf> classification.

Vegetation Community.

See Community.

Vegetation Description.

See Vegetation Characterization.

Vegetation (Field) Key.

See Dichotomous Field Key.

Vegetation Mapping. The process of identifying, classifying, and locating vegetation communities using real world coordinates.

Vegetation Structure. See Structure.

Vegetation Type. See Type.

Vertical Aerial Photography.

See Aerial Photography.

Wetland. A community or landscape type that is characterized by either hydric soils or hydrophytic plants or both. A wetland may be vegetated or non-vegetated.

APPENDIX A

A. CD-Rom Readme Text and CD-Rom

The following is the text of the Readme.doc document for the CD-Rom that accompanies this report. This CD-Rom contains all coverages and GIS data developed for the SUCR vegetation map, databases for vegetation classification relevés and accuracy assessment observations, field photos, report files, and associated metadata. The associated metadata describes the attributes in all of the coverages and databases. We also include a list of appropriate citations below each of the coverages or databases to be used when citing these sources.

The files are arranged on the CD-Rom as follows:

Readme.doc – This file

1. Ancillary_Data Folder - This folder contains 4 subfolders with information on the park, project, and imagery boundary files. Each subfolder contains a coverage in Arc/Info export format (.e00), a shape file, a coverage, and associated metadata:
 - a. Flightline_bndry- Flightline boundaries used to develop the aerial photography
Citation:
U.S. Bureau of Reclamation Remote Sensing and GIS Group. 2004. Flight Line Coverage: Sunset Crater Volcano National Monument. A digital spatial database (ArcInfo). U.S. Geological Survey.
 - b. Park_bndry- Boundary of Sunset Crater Volcano National Monument
Citation:
Flagstaff Area National Monuments. 2004. Boundary: Sunset Crater Volcano National Monument, AZ. A digital spatial database (ArcInfo). U.S. Geological Survey.
 - c. Proj_bndry- Boundary for vegetation map for Sunset Crater Volcano National Monument
Citation:
U.S. Bureau of Reclamation Remote Sensing and GIS Group. 2004. Project Boundary: Sunset Crater Volcano National Monument Vegetation Mapping Project. A digital spatial database (ArcInfo). U.S. Geological Survey.
 - d. Quad_Doqq_bndry-Boundary of the USGS topographic quadrant maps for Sunset Crater Volcano National Monument
Citation:
U.S. Bureau of Reclamation Remote Sensing and GIS Group. 2004. Boundary: Flagstaff Area National Monuments USGS Quadrangles and DOQQs. A digital spatial database (ArcInfo). U.S. Geological Survey.
2. Basemap folder – This folder contains the MrSid compressed mosaic of the DOQQs and associated metadata for Sunset Crater National Monument. The MrSid images can be viewed as images in ArcView using the MrSid extension.
Citation:
U.S. Geological Survey. 2004. DOQQ Basemap: Sunset Crater Volcano National Monument. Digital orthophotoquads. U.S. Geological Survey.

3. Ground Photos (.tif/.jpeg) - This folder contains photos for each relevé collected for the vegetation classification. Each photo is listed as “SC-***a/b/c” where the SC stands for Sunset Crater, the *** indicates the relevé number, and either a, b, or c is listed after the prefix corresponding sequentially to the number of photos taken at each relevé point. For example, at relevé number SC-032 two photos were taken and are listed as SC-032a and SC-032b. For additional information on the aspect and time of the photo taken at each relevé refer to the Vegetation Relevé Database described below.
4. Map_Demo – This folder contains an ArcView project file (.apr), associated data that was used to create the final vegetation map, graphics associated with printing the vegetation map, and a readme.txt file. To open the project, a copy of this folder must be placed on your hard drive. You will also need the ArcPress extension. Start ArcView and then navigate to the project file (Sucr_demo.apr). Further information can be found in the included readme.txt. To print the vegetation map, a graphic of the map can be found under the Vegetation_Map folder, under the Graphics folder, and in the Map_Demo folder. In the HP_RTL folder an ArcPress extension (sucr_veg.rtl) will allow you to directly print the map layout to a plotter. In the MS_Bitmap folder a graphic (sucr_veg.bmp) will also allow you to print out the map.
5. Project_Report – This folder contains the entire final project report (SUCR_Final_Report.pdf) in an Adobe Acrobat format.
6. Vegetation_Data – This folder contains all the spatial data (final vegetation GIS cover including a vegetation map clipped to the park boundary, observation points, aspen cover, accuracy assessment points, classification relevé points, and off road vehicle cover) and databases (Vegetation Relevé Database and Accuracy Assessment Database) used to create the final vegetation map as well as associated metadata.
 - a. Accuracy Assessment
 1. Database- Microsoft access database named SUCR_AAdatabase.mdb with accuracy assessment data
Citation:
Hansen, M. and K. Thomas. 2004. Sunset Crater Volcano National Monument: Accuracy Assessment. A MS Access database. U.S. Geological Survey.
 2. Metadata-All associated metadata for the spatial data and database
 3. Spatial data- A coverage and shapefile of the accuracy assessment points used in the accuracy assessment analysis
 4. sucr_aa_pts.e00-An Arc/Info export format (.e00) of the accuracy assessment points
Citation:
Dale, B., M. Hansen, and K. Thomas. 2004. Accuracy Assessment Points: Sunset Crater Volcano National Monument. A digital spatial database (ArcInfo). U.S. Geological Survey.
 - b. Aspen_Map
 1. Metadata-Associated metadata for the spatial data

2. Spatial data- A coverage and shapefile of the occurrence of aspen in the Sunset Crater Vegetation Mapping Project
3. sucr_aspen.e00-An Arc/Info export format (.e00) of the cover of aspen in the project boundary

Citation:

U.S. Bureau of Reclamation Remote Sensing and GIS Group. 2004. Aspen Coverage: Sunset Crater Volcano National Monument Vegetation Mapping Project. A digital spatial database (ArcInfo). U.S. Geological Survey.

c. Clip_Veg

1. Metadata- Associated metadata for the spatial data
2. Spatial data- A coverage and shapefile of the vegetation map clipped to the Sunset Crater Volcano National Monument boundary
3. sucr_clip_veg.e00-An Arc/Info export format (.e00) of the cover of vegetation map clipped to the Sunset Crater Volcano National Monument boundary

Citation:

U.S. Bureau of Reclamation Remote Sensing and GIS Group. 2004. Clipped Vegetation Coverage: Sunset Crater Volcano National Monument Vegetation Mapping Project. A digital spatial database (ArcInfo). U.S. Geological Survey.

d. Observation_Points

1. Metadata- Associated metadata for the spatial data
2. Spatial data- A point coverage and shapefile of the observation points used to help with the photointerpretative work
3. sucr_obs.e00- An Arc/Info export format (.e00) of the observation points collected in the field to help with the photointerpretative work

Citation:

U.S. Bureau of Reclamation Remote Sensing and GIS Group. 2004. Observation Point Coverage: Sunset Crater Volcano National Monument Vegetation Mapping Project. A digital spatial database (ArcInfo). U.S. Geological Survey.

e. OHV_Map

1. Metadata- Associated metadata for the spatial data
2. Spatial data- A point coverage and shapefile of the off highway vehicle tracks are embedded within and can be identified in the coverage or shapefile relational table.
3. sucr_obs.e00- An Arc/Info export format (.e00) of the area where off highway vehicle tracks were evident in the project area. Areas with no evident tracks are embedded within and can be identified in the coverage or shapefile relational table

Citation:

U.S. Bureau of Reclamation Remote Sensing and GIS Group. 2004. Off Highway Vehicle Use: Sunset Crater Volcano National Monument. A digital spatial database (ArcInfo). U.S. Geological Survey.

f. Releve_Plots

1. Database- Microsoft access database named SUCR_FieldReleve_data-base.mdb with all the information collected in the field at each classification relevé

Citation:

Hansen, M. and K. Thomas. 2004. Field Relevé Plots: Sunset Crater Volcano National Monument. A MS Access database. U.S. Geological Survey.

2. Metadata- Associated metadata for the database and spatial data
3. Spatial data- A coverage and shapefile of the classification relevés
4. sucr_releve.e00-An Arc/Info export format (.e00) of the cover of classification relevé points sampled in the Sunset Crater project boundary

Citation:

Hansen, M. and K. Thomas. 2004. Field Relevé Plots: Sunset Crater Volcano National Monument Vegetation Mapping Project. A digital spatial database (ArcInfo). U.S. Geological Survey.

g. Vegetation_Map

1. Metadata- Associated metadata for the spatial data
2. Spatial data- A coverage and shapefile of the vegetation map for the Sunset Crater Volcano National Monument and the project environs
3. sucr_veg.e00-An Arc/Info export format (.e00) of the cover of the vegetation map coverage

Citation:

U.S. Bureau of Reclamation Remote Sensing and GIS Group. 2004. Sunset Crater Volcano National Monument Vegetation Map. A digital spatial database (ArcInfo). U.S. Geological Survey.

APPENDIX B

B. Precipitation and Temperature Averages for Sunset Crater Volcano National Monument (August and January 1971-2002)

Precipitation data from www.ncdc.noaa.gov/ol/climate/online/coop-precip.html
for the Sunset Crater reporting station. (Internet Access January 2002)

Temperature data from www.ncdc.noaa.gov/ol/climate/climatedata.html for the Flagstaff area.
(Internet Access January 2002)

MACRO TOPOGRAPHY

- 00 INTERFLUVE(crest, summit, ridge): linear top of ridge, hill, or mountain; elevated area between two fluves
- 01 HIGH SLOPE(shoulder slope, upper slope, convex creep slope): the top of a slope, convex
- 02 HIGH LEVEL(mesa): top of plateau
- 03 MIDSLOPE(transportational midslope, middle slope): intermediate slope
- 04 BACKSLOPE(dipslope): subset of midslopes which are steep, linear, and cliff segments
- 05 STEP IN SLOPE(ledge, terracette): nearly level shelf interrupting a steep slope, rock wall, or cliff face
- 06 LOWSLOPE(lower slope, foot slope, colluvial footslope): inner gently inclined surface at the base of a slope, concave
- 07 TOESLOPE(alluvial toeslope): outermost gently inclined surface at base of slope, commonly gentle and linear
- 08 LOW LEVEL(terrace): valley floor or shoreline representing the former position of an alluvial plain, lake or shore
- 09 CHANNEL WALL(bank): sloping side of a channel
- 10 CHANNEL BED(narrow valley bottom, gully arroyo): bed of single or braided watercourse commonly barren of vegetation
- 11 BASIN FLOOR(depression): nearly level to gently sloping, bottom surface of a basin

LANDFORM

- 20 **Rockpile**=uplands composed primarily of jointed and exfoliating granitic outcrops
- 21 **Bajada**=alluvial slopes of fans that accumulate at the base of a desert mountain or mountain canyons that are interrupted by the trenching of minor water sources
- 22 **Drainage Channel**=bottom not side slope of a drainage confined by banks or a canyon
- 23 **Valley Bottom Fill**=usually level places
- 24 **Playa**=Pleistocene dried lakebed often with some surface water
- 25 **Side Slope**=side of drainage channels
- 26 **Lower Slope**=lower better watered portion of a slope
- 27 **Mid Slope**=central portion of a slope
- 28 **Upper Slope**=the upper driest portion of a slope
- 29 **Interfluvium**=the area between small drainage channels
- 30 **Ridge**=high ground between two opposing slopes
- 31 **Slick Rock**=large exposed expanses of bedrock
- 32 **Terrace**=level or gently sloping shelf perched on a slope, often caused by down-cutting rivers
- 33 **Mesa**=level or gently sloping ground surrounded on 3 or more sides by steep down slopes and capped
- 34 **Butte**=similar to a mesa, except with a top that does not have a flat configuration
- 35 **Cliff**=very steep rock slopes
- 36 **Talus**=unsorted material resulting from mass wasting of steep mountain slopes
- 37 **Sand Dune/Sand Sheet**=large accumulations of sand, may be stable or unstable (moving)

APPENDIX E

E. Field Key for the Sunset Crater Volcano National Monument Vegetation Community Descriptions and Map Classes

1. Site characterized by sparsely vegetated substrate (<2%) or by infrastructure. (go to 23)
1. Site with greater than 2% vegetation, may be within lava bed, cinder, scree, or rock outcrop. (go to 2)
2. Site characterized by tree and/or shrub cover. (go to 3)
2. Site characterized by grasses and forbs, trees may be present. (go to 15)
3. Site characterized by trees. (go to 4)
3. Site characterized by shrubs. (go to 19)

TREES

4. Site an island of vegetation within a lava bed or at the edge of lava beds. Map Class: **Lava Beds Sparse Vegetation**. Association is *Populus tremuloides* or *Pinus ponderosa* in the overstory and *Fallugia paradoxa* and/or *Holodiscus dumosus* in the understory. ***Pinus ponderosa* - (*Populus tremuloides*) / *Fallugia paradoxa* - (*Holodiscus dumosus*) Lava Bed Sparse Vegetation**. (see picture below)

4. Site not as above. (5)
5. Trees mostly evergreen. (6)
5. Trees mostly deciduous. Dominant tree is *Populus tremuloides*. This is often less than 0.5ha and is combined with adjacent vegetation communities in the vegetation map. Association is ***Populus tremuloides* / Cinder Woodland (Local Assemblage)**. (see picture below) However, a separate coverage, SUCR_aspen, shows some photointerpreted occurrences for this association.

6. Dominant tree is *Pinus ponderosa*. *Pinus edulis*, *Juniperus osteosperma* or *J. deppeana* may be present and with equal cover. *Pseudotsuga menziesii* may be present, but with less cover than *Pinus ponderosa*. (7)
6. Dominant tree species not *Pinus ponderosa* or if so, *Pseudotsuga menziesii* is co-dominant. (12)
7. Herbaceous cover greater than 5% and is the dominant understory lifeform. Shrub cover generally less than 10% and not dominated by *Fallugia paradoxa*. If shrub cover more than 10%, it is still less than the herbaceous cover. (8)
7. Shrub cover dominated by *Fallugia paradoxa* or all understory cover (shrubs and grasses combined) 5% or less. (11)
8. Herbaceous cover is dominated by *Andropogon hallii*.
Map Class: **Ponderosa Pine / Sand Bluestem Woodland**. (see picture below)
Association is ***Pinus ponderosa* / *Andropogon hallii* Woodland**.

8. Dominant grass not as above. (9)
9. Herbaceous cover is dominated by *Bouteloua gracilis*. *Muhlenbergia montana*, is not present or has very low cover (<2%). Map Class: **Ponderosa Pine/Montane Grass Mosaic**. (see picture below) Association is ***Pinus ponderosa* / *Bouteloua gracilis* Woodland**.

9. *Bouteloua gracilis* not dominant or if so, *Muhlenbergia montana* with equal or greater cover than *Bouteloua gracilis*. (10)
10. Herbaceous cover is often dominated by *Muhlenbergia montana*. *Bouteloua gracilis*, if present, can co-dominate, but often has less cover than *Muhlenbergia montana*. Map Class: **Ponderosa Pine/Montane Grass Mosaic**. (see picture below) Association is ***Pinus ponderosa* / *Muhlenbergia montana* Woodland**.

10. Herbaceous cover is dominated by non-native exotic species such as *Bromus tectorum* and/or *Linaria dalmatica* ssp. *dalmatica* and/or native disturbance following species such as *Artemisia dracunculus*. Map Class: **Ponderosa Pine Invasive Herbaceous Vegetation**. (see picture below) Association is *Pinus ponderosa* Wooded Invasive Herbaceous Vegetation (Local Assemblage).

11. Shrub cover greater than 5% and dominated by *Fallugia paradoxa*. Some areas may also contain high cover of *Ericameria nauseosa*. Map Class: **Ponderosa Pine / Apache Plume Woodland**. (see picture on left below) If *Pinus edulis* is greater than 10% then the modifier “pinyon” applies. If total cover is less than 25% then the modifier “sparse” applies. (see picture on right below) Association is *Pinus ponderosa* / *Fallugia paradoxa* Woodland.

11. Shrub and herbaceous cover generally less than 5% total. Map Class: **Ponderosa Pine / Cinder Woodland**. (see picture below) Association is *Pinus ponderosa* / Cinder Woodland.

12. Dominant tree species is *Pinus flexilis*. *Pseudotsuga menziesii*, if present, has less cover than *Pinus flexilis*. Map Class: **Limber Pine Woodland**. (see picture below) Association is ***Pinus flexilis* Woodland Alliance**.

12. Dominant tree species is not *Pinus flexilis* or is *Pinus flexilis* with *Pseudotsuga menziesii* co-dominating. (13)
13. Dominant or associated dominant tree species is *Pseudotsuga menziesii*. *Pinus flexilis* or *Pinus ponderosa* may be present and have equal cover to *Pseudotsuga menziesii*. Map Class: **Douglas-fir Forest**. (see picture below) Association has herbaceous understory dominated by *Muhlenbergia montana*: ***Pseudotsuga menziesii* / *Muhlenbergia montana* Forest**, otherwise ***Pseudotsuga menziesii* Forest Alliance**. (No picture available)
13. Dominant tree species is *Pinus edulis*. *Juniperus osteosperma* may be co-dominant but does not need to be present. *Juniperus deppeana* may be present. Map Class: **Pinyon Pine – Utah Juniper / Blue Grama Woodland**. (see picture below) If total cover is less than 25% then the modifier “sparse” applies. Continue key to vegetation association (14)

14. *Juniperus osteosperma* or *Juniperus deppeana* are present. Herbaceous cover, if present, characterized by *Bouteloua gracilis*. Association is ***Pinus edulis* – (*Juniperus osteosperma*) / (*Bouteloua gracilis*) Woodland**. (see picture below)

14. Neither *Juniperus osteosperma* or *Juniperus deppeana* are present. Association is ***Pinus edulis* / Sparse Understory Forest.** (see picture below)

GRASSES

15. Dominant grass is *Andropogon hallii*. Map Class: **Sand Bluestem Herbaceous Vegetation.** (see picture below) Association is ***Andropogon hallii* Colorado Plateau Herbaceous Vegetation.**

15. Dominant grass not as above. (16)
16. Herbaceous cover is dominated by *Bouteloua gracilis*. *Muhlenbergia montana*, if present, has less cover than *Bouteloua gracilis*. Map Class: **Montane Grassland.** (see picture below) If *Ericameria nauseosa* is greater than 10% then the modifier “rabbitbrush” applies. If the site is in Bonito Park then the modifier “Bonito Park” applies. Association: ***Bouteloua gracilis* Herbaceous Vegetation.**

16. Dominant grass not as above. (17)
17. Herbaceous cover is dominated by *Muhlenbergia montana*, *Bouteloua gracilis*, if present, has less cover than *Muhlenbergia montana*. Map Class: **Montane Grassland**. (see picture below) If *Ericameria nauseosa* is greater than 10%, then the modifier “rabbitbrush” applies. If the site is in Bonito Park then the modifier “Bonito Park” applies. Association is ***Muhlenbergia montana* Herbaceous Vegetation**.

17. Dominant grass not as above (18).
18. Herbaceous cover is dominated by *Pascopyrum smithii*. Map Class: **Ponderosa Pine Invasive Herbaceous Vegetation**. (see picture below) Association is ***Pascopyrum smithii* Herbaceous Vegetation**.

18. Herbaceous cover is dominated by non-native exotic species such as *Bromus tectorum* and/or *Linaria dalmatica* ssp. *dalmatica*. Native disturbance following species such as *Artemisia dracunculus* may also be present. *Pinus ponderosa* present but cover less than herbaceous cover. Map Class: **Ponderosa Pine Invasive Herbaceous Vegetation**. (see picture below) Association is ***Pinus ponderosa* Wooded Invasive Herbaceous Vegetation (Local Assemblage)**.

SHRUBS

19. *Eriogonum corymbosum* is the dominant shrub. *Andropogon hallii* also present. Map Class: **Wild Buckwheat – Sand Bluestem Sparse Vegetation**. (see picture below) Association is *Eriogonum corymbosum* Cinder Sparse Vegetation.

19. Dominant shrub not as above. (20)
20. *Fallugia paradoxa* is the dominant shrub. Map Class: **Apache Plume / Cinder Sparse Vegetation**. (see picture below) Association is *Fallugia paradoxa* (*Atriplex canescens*, *Ephedra torreyana*) Cinder Sparse Vegetation.

20. Dominant shrub not as above. (21)
21. *Rhus trilobata* is the dominant shrub. *Pinus ponderosa* is also present with low cover (up to 5%). This is often less than 0.5ha and was combined with adjacent vegetation communities for the vegetation map. Association is *Pinus ponderosa* / *Rhus trilobata* **Shrubland (Local Assemblage)**. (see picture below) (Continue key to surrounding vegetation community for map class)

21. Dominant shrub not as above and occurring on lava and basalt outcrops. Map Class: **Rock Outcrop and Scree Shrubland**. Continue key to get to vegetation association (22).
22. *Holodiscus dumosus* is the dominant shrub. Found on basaltic and cinder scree. Association is **Fallugia paradoxa – Brickellia grandiflora – (*Holodiscus dumosus*) Scree Shrubland (Local Assemblage)**. (see picture below)

22. *Ericameria nauseosa* and *Pericome caudata* are the dominant shrubs. Found on lava and basalt outcrops. Association is ***Ericameria nauseosa*-*Pericome caudata* Rock Outcrop Sparse Vegetation (Local Assemblage)**. (see picture below)

SPARSE VEGETATION

23. Site characterized by sparsely vegetated cinder or lava. (24)
23. Site characterized by land use. (25)
24. Substrate loose cinder. Map Class: **Cinder Barren Sparse Vegetation**. (see picture below)

24. Substrate lava. Map Class: **Lava Beds.** (see picture below)

25. Site characterized by land use. Map Classes below.
- a. **Croplands and pastures**
 - b. **Facilities**
 - c. **Recreational tracks:** This map class occurs often as linear polygons within many of the map classes on the vegetation map. These tracks are easily identified in the aerial photography and were included as a separate coverage, suc_r_OHV.
 - d. **Residential land**
 - e. **Strip Mines, Quarries, Gravel Pits**
 - f. **Transportation, communications and utilities**
 - g. **Reservoirs and Trick Tanks**

APPENDIX F

F. National Vegetation Classification Standard (NVCS) Local Descriptions for Sunset Crater Volcano National Monument

(Kathryn Thomas and Monica Hansen of the USGS Colorado Plateau Research Station collected, analyzed, and initially classified field relevé data. Marion Reid and Keith Schulz of NatureServe reviewed and finalized local classification and compiled global classification.)

The following vegetation descriptions are derived from the 114 vegetation relevés sampled throughout the course of this project. Global information, information based on reports throughout the distribution of the associations/alliances, was also compiled by NatureServe to augment the local descriptions. All of the vegetation association descriptions will include information on both the global and local descriptions, unless the associations have only been described from Sunset Crater Volcano National Monument.

The vegetation descriptions are separated into twelve sections. Many of the sections are subdivided into a ‘Sunset Crater Volcano National Monument’ and a ‘Globally’ section. After the Sunset Crater Volcano National Monument subheading information follows on the association/alliance as it appears in the park, the local information. After the Globally subheading information follows on the association/alliance as it appears throughout its range. Information about each of the sections is described in Table 1.

Table 1. Explanations on the vegetation descriptions sections.

Vegetation Description Sections	Explanation
Classification Confidence Level	The classification confidence level identified by NatureServe.
USFS Wetland System	The U.S. Department of Agriculture – Forest Service wetland classification system ranking crosswalked to NVCS associations, provided by NatureServe.
Range	The range describes where this association was mapped in the project area, information on where particular relevés were sampled, and where the association occurs throughout its entire range.
Environmental Description	Environmental description describes the abiotic conditions measured related to the association/alliance. In the local descriptions, all slopes are described as a range of elevation (lowest to highest elevation) as well as an average elevation across all of the relevés measured in meters (m).
Most Abundant Species	This section identifies the dominant and/or indicator species for Sunset Crater Volcano National Monument and globally throughout its range.
Associated Species	Associated species describes the most common species associated with all of the relevés locally and globally.
Vegetation Description	This section identifies the vegetation characteristics specific to the association/alliance. Locally, total vegetation cover is described as absolute percent cover and is given as a range (lowest to highest % cover) and average across all of the relevés. Diameter Base Height (DBH) is provided in centimeters (cm) if trees were present in the relevés.

Conservation Rank	The conservation rank is a ranking system used to identify and prioritize conservation areas applied to NVCS associations by NatureServe. The global conservation rank is described in Table 2.
Database Code	Database codes are a unique code that NatureServe developed to organize and identify the vegetation associations.
Map Classes	Map classes describes how the association is crosswalked to the map class, a general description of where the map class occurs, and the total number of hectares and polygons occurring inside and outside Sunset Crater Volcano National Monument.
Comments	Comments particular to the vegetation description locally at Sunset Crater Volcano National Monument and globally.
References	References identified in the vegetation description.

Table 2. Conservation ranking system for associations.

Global Conservation Rank	% of Associations
GX – Eliminated	0
GH – Presumed eliminated (historic)	<1
G1 – Critically imperiled	10
G2 – Imperiled	18
G3 – Vulnerable	22
G4 – Apparently secure	16
G5 – Secure	8
GU – Unrankable	3
G? – Unranked	22

Pinus edulis / Sparse Understory Forest

COMMON NAME	Two-needle Pinyon / Sparse Understory Forest
PHYSIOGNOMIC CLASS	Forest (I.)
PHYSIOGNOMIC SUBCLASS	Evergreen forest (I.A.)
PHYSIOGNOMIC GROUP	Temperate or subpolar needle-leaved evergreen forest (I.A.8)
PHYSIOGNOMIC SUBGROUP	Natural/Semi-natural Temperate or subpolar needle-leaved evergreen forest (I.A.8.N)
FORMATION	Rounded-crown temperate or subpolar needle-leaved evergreen forest (I.A.8.N.b)
ALLIANCE	<i>Pinus edulis</i> Forest Alliance

CLASSIFICATION CONFIDENCE LEVEL Strong

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Two-needle Pinyon / Sparse Understory Forest occurs on cinder cones in the park environs adjacent to the Sunset Crater Volcano NM boundaries. Within the environs of the project study boundary this vegetation type was mapped within the San Francisco volcanic field on the northern and eastern slopes of various unnamed cinder cones and also on Black Mountain. Only one representative stand was sampled in our study, on the northeastern slope of O'Leary peak.

Globally

These woodlands are found locally on the Colorado Plateau, but likely are more widespread and occur throughout the range of *Pinus edulis*.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

This association occurs mostly on the steep cooler slopes of the northern and eastern cinder cones. The one representative stand had 55% slope, an elevation of 2,200m, and occurred on fine cinder soils.

Globally

These forests and woodlands occur in foothills, mesas, plateaus and mountains of New Mexico, Arizona and Utah. Sites are flat to moderately sloping at elevations that range from 1,980-2,290 m (6,500-7,500 feet). Stands frequently occur on less xeric, northern and eastern exposures, but it can occur on all aspects. Substrates are variable but often include eroded, shallow or coarse-textured substrates such as cinder (but not rock outcrops) that limit the growth of understory shrubs and herbaceous plants. Cover of tree litter is dense in some stands (Kennedy 1983). The original concept of this association included stands on relatively mesic sites with high tree growth potential that produced a dense tree canopy, which shades out the understory vegetation. However, the association also includes fire-suppressed stands and woodlands growing on eroded or "badlands" substrates and/or over-grazed stands that lack understory vegetation (Baker et al. 1995, Stuever and Hayden 1997a and b).

Globally

Juniperus scopulorum, *Juniperus deppeana*, *Ageratina herbacea*, *Cercocarpus montanus*, *Fallugia paradoxa*, *Rhus trilobata*, *Gutierrezia sarothrae*, *Achnatherum hymenoides*

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Only one relevé was classified as *Pinus edulis* sparse understory forest, where the total vegetation cover is 70% with 63% within the tree layer, 6% within the shrub layer, and 11% within the herbaceous layer.

Within the one relevé, mature *Pinus edulis* had a cover of 62%. The DBH ranged from 17-50cm (average 32cm).

Twenty-one species of shrubs and herbs were measured within this association. The most common shrubs were *Ageratina herbacea* and *Fallugia paradoxa*, both with less than 4% of the total cover.

Globally

This plant association is characterized by a moderate (over 25% cover) to dense tree canopy with little or no understory. The tree canopy is dominated by *Pinus edulis*. Other trees may co-dominate especially one or more species of *Juniperus* that vary with geography, such as *J. monosperma*, *J. osteosperma*, *J. scopulorum* or *J. deppeana*. If other species of *Pinus* are present they do not co-dominate. The sparse understory (<10% cover and usually <2%) may include scattered shrubs, dwarf-shrubs, succulents, grasses and forbs such as *Ageratina herbacea*, *Cercocarpus montanus*, *Fallugia paradoxa*, *Rhus trilobata*, *Gutierrezia sarothrae*, *Achnatherum hymenoides* and species of *Opuntia*, *Yucca*, *Poa*, *Penstemon*, and *Phlox*.

CONSERVATION RANK G5

DATABASE CODE C EGL000795

MAP CLASSES

Two-needle Pinyon / Sparse Understory Forest is mapped as part of the Pinyon Pine – Utah Juniper / Blue Grama Woodland map class which corresponds to map codes 11 and 12

The map class Pinyon Pine - Utah Juniper / Blue Grama Woodland occurs mainly on the northern and eastern section of the project boundary. The total area mapped within Sunset Crater Volcano NM is 2 hectares within 5 polygons and the total area in the park environs is 394 hectares within 59 polygons.

COMMENTS

Sunset Crater Volcano National Monument

The Pinyon / Sparse Understory Forest is distinct with a high canopy cover of Pinyon, absence of Utah Juniper, and a sparse understory. This type grades into the Pinyon (Juniper) / Blue Grama Woodland association at lower elevations with less steep slopes; however, due to difficulty in photointerpretation, the two associations have been combined into one map class: Pinyon Pine – Utah Juniper / Blue Grama Woodland.

Global Comments

The original concept of this plant association had a nearly closed tree canopy with a sparse, shaded understory growing on relatively mesic sites. These forests may actually be a product of fire suppression, livestock grazing removal of fine fuels, and/or soil erosion, and may be present in degraded examples of other *Pinus edulis* associations (Stuever and Hayden 1997a and b). The association concept has been expanded to include more open-growing stands by Muldavin et al. (2000) who included stands under 20% tree cover

Global Dynamics

Pinus edulis is extremely drought-tolerant and slow-growing (Little 1987, Powell 1988, Muldavin et al. 1998a). It is also non-sprouting and may be killed by fire. However, fire frequency is relatively low because of the lack of continuous fine fuel needed to spread ground fire. When fire occurs, it will likely be severe, occurring under the extreme conditions (high winds) needed to carry a crown fire (Bradley et al. 1992, Wright et al. 1979). Active fire suppression and historic grazing by livestock (which has removed the fine fuels that carry fire) have likely altered natural fire regimes and may have contributed to the conversion of open woodlands to closed tree canopies with sparse understories. Subsequent erosion of bare soil can be expected to reduce site productivity (Baker et al. 1995).

CLASSIFICATION CONFIDENCE LEVEL Alliances are not ranked by NatureServe for classification confidence

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Douglas-fir Forest is mapped on the cooler northern slopes of O'Leary Peak and on the top of Darton Dome. Only one relevé was sampled and it occurred in a cold air-drainage on the western slope of O'Leary Peak.

Globally

This montane and coastal alliance includes evergreen forests dominated by *Pseudotsuga menziesii* occurring from Vancouver Island south through the Cascades and coastal ranges of northern California, through the Rocky Mountains, the Nevada-Utah mountains, the Arizona-New Mexico mountains, to extreme western Texas and northern Mexico.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

Douglas-fir Forest was sampled at an elevation of 2,600m on a steep slope (40%).

Globally

Forest associations within this alliance occur in two major distributions. The first is along the northwest Pacific slope in low-elevation valleys of western Oregon and Washington, in scattered dry sites of the Olympics and western Cascades, and along the eastern slope of the Oregon and Washington Cascades. The second is in the Rocky Mountains, extending from the Okanogan Highlands and Blue Mountains of eastern Washington and Oregon south and east into the mountains of the Great Basin and into the Rocky Mountains from Montana south into northern Mexico.

The Pacific Northwest region has mild winter temperatures, cool to hot summers, and receives 75-250 cm of annual precipitation in a Mediterranean pattern of winter rain followed by summer drought. The majority of the precipitation falls as rain, but snowfall can be abundant at montane elevations. These forests occur along low- to moderate-elevation (0-1300 m) mountain slopes and valley margins, with an increasing affinity for moist topographic positions away from the coast and southward. They occupy sites where soil drought is induced by site features (shallow soils, sunny aspect) or local rainshadow effects that lessen precipitation. Generally these forests are in drier sites or zones than *Pseudotsuga menziesii* - *Abies grandis* forests but more moist sites or zones than *Pinus ponderosa* - *Pseudotsuga menziesii* woodlands. Contiguous vegetation is often *Quercus* spp. woodlands and savannas, chaparral, or annual grasslands at the xeric margin, and closed *Sequoia sempervirens* or *Tsuga heterophylla* forests at the mesic margin.

Pseudotsuga menziesii forests found in the Rocky Mountains occur under a comparatively drier and more continental climate regime, and at higher elevations than in the Pacific Northwest. Elevations range from less than 1000 m in the northern Rocky Mountains to nearly 2900 m in the southern Rockies and plateaus of the southwestern U.S. Lower elevation stands typically occupy protected northern exposures or mesic ravines and canyons, often on steep slopes. At higher elevations, these forests occur primarily on southerly aspects or ridgetops. Precipitation ranges from 50-100 cm with moderate snowfall and with a greater proportion falling during the growing season.

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

Monsoonal summer rains can contribute a significant proportion of the annual precipitation in Arizona, New Mexico, and Colorado. Adjacent vegetation is typically dominated by *Pinus ponderosa* or *Pinus flexilis* (in Idaho and Montana) on drier, warmer sites; *Picea* spp. on more moist sites; *Abies concolor* (in New Mexico and Arizona) or *Abies lasiocarpa* at higher, cooler sites. Montane grasslands and meadows may also occur in patches within these forests, or on adjacent dry slopes.

Soils are highly variable across the range of this alliance and derived from diverse parent materials. *Pseudotsuga menziesii* forests are reported by most studies (Lillybridge et al. 1995, Steele et al. 1981, Pfister et al. 1977, Mauk and Henderson 1984) to show no particular affinities to geologic substrates. Rock types can include marine sediments in northern California and Oregon, glacial deposits in the Puget Sound, extrusive volcanics in the Cascades and Columbia Basin, and sedimentary rocks in the central and southern Rockies and the Colorado Plateau. The soils are typically slightly acidic (pH 5.0-6.0), well-drained, and well-aerated. They can be derived from moderately deep colluvium or shallow jointed bedrock, and are usually gravelly or rocky.

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Only one relevé was sampled within the Douglas-fir Forest alliance. The total vegetation cover was 70% with 65% in the tree layer, 4% in the shrub layer, and 1% in the herbaceous layer. Fifteen species were found on the relevé, most with low cover.

Tree canopy was co-dominated by *Pseudotsuga menziesii* (35%) and *Pinus flexilis* (30%). *Pseudotsuga menziesii* DBH ranged from 12-65 cm (average 35 cm) and *Pinus flexilis* ranged from 11.5-31 cm (average 16.2 cm). Fifty to sixty-five percent of the trees in the relevé were 10-30 meters tall, with the remainder 10 meters or shorter.

The shrub layer was characterized by *Ribes cereum* and *Holodiscus dumosus*. The herbaceous layer was nearly absent (~1% total cover).

Globally

This alliance includes evergreen forests dominated by *Pseudotsuga menziesii* occurring in mountain ranges of western U.S., as well as northern Mexico, and western Texas. In the Pacific ranges the dominant species is *Pseudotsuga menziesii* var. *menziesii*, while *Pseudotsuga menziesii* var. *glauca* is the dominant in forests of the Rocky Mountains, south to Mexico.

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

On the eastside of the Cascades and east into the northern and southern Rocky Mountains, these forests are dominated by *Pseudotsuga menziesii* in the canopy and almost always in the tree regeneration layer. *Pinus ponderosa* is an important seral species occurring in many associations, either as older seral remnants or codominating in the canopy. Other trees that can be present to abundant (but which are typically seral) include *Larix occidentalis* in the northern Rockies, *Populus tremuloides*, (in the southern Rockies and south into New Mexico and Arizona), *Pinus strobiformis* or *P. flexilis* (in New Mexico and Arizona), and *Pinus contorta* (throughout much of the alliance's range). Species of *Abies* and *Picea* do not commonly occur in this alliance, but are present in some stands.

Understories in *Pseudotsuga menziesii* forests are varied; many associations have well-developed shrub layers, varying in height from <2 m (typically), up to 5 m. Dominant species in some associations in the northern Rockies include *Acer glabrum*, *Linnaea borealis*, *Paxistima myrsinites*, *Physocarpus malvaceus*, *Symphoricarpos albus*, *Symphoricarpos oreophilus*, *Spiraea betulifolia*, *Vaccinium caespitosum*, and *Vaccinium membranaceum*. Further south other shrubs become the dominant or diagnostic species, such as *Acer grandidentatum*, *Amelanchier alnifolia*, *Arctostaphylos patula*, *Jamesia americana*, *Physocarpus monogynus*, *Quercus arizonica*, *Quercus gambelii*, *Quercus rugosa*, *Quercus X pauciloba*, and *Quercus hypoleucoides*. *Arctostaphylos uva-ursi* and *Mahonia repens* are present to important throughout the range.

The herbaceous layer can be sparse, or if the shrub layer is not abundant, can be relatively species-rich, usually graminoid-dominated. Important or dominant species include the graminoids *Bromus ciliatus*, *Calamagrostis rubescens*, *Carex geyeri*, *Carex rossii*, *Festuca arizonica*, *Festuca occidentalis*, *Bromus ciliatus*, *Luzula parviflora*, *Muhlenbergia montana*, and *Muhlenbergia virescens* and the forbs *Arnica cordifolia*, *Osmorhiza berteroi*, *Thalictrum occidentale*, *Viola adunca*, and species of many other genera, including *Lathyrus*, *Penstemon*, *Erigeron*, *Lupinus*, *Fragaria*, *Vicia*, *Arenaria*, *Galium*, and others.

In the low elevation forests of western Washington and Oregon (west of the Cascade crest) the canopy is semi-open to closed. *Pseudotsuga menziesii* dominates with little or no *Tsuga heterophylla* or *Thuja plicata*. *Abies grandis* is codominant on some sites, and *Pinus contorta* can also codominate. *Salix scouleriana* and *Arbutus menziesii* are common but subordinate. There is a well-developed understory of deciduous or evergreen shrubs, or graminoids. *Holodiscus discolor*, *Symphoricarpos albus*, or *Rosa gymnocarpa* are typical dominant species and diagnostic. Other shrubs that may be important include *Gaultheria shallon*, *Rhododendron macrophyllum*, *Vaccinium ovatum*, *Mahonia aquifolium* (= *Mahonia piperiana*), *Mahonia nervosa*, *Corylus cornuta*, and *Symphoricarpos mollis*. In the herbaceous layer *Festuca occidentalis*, and *Melica subulata* are diagnostic species which are often dominant or codominant. *Bromus vulgaris*, *Festuca subuliflora*, and *Elymus glaucus* are also very common.

DATABASE CODE A.157

MAP CLASSES

Pseudotsuga menziesii Forest Alliance is mapped as map class Douglas-fir Forest, map code 21. The map class Douglas-fir Forest includes both the *Pseudotsuga menziesii* Forest Alliance and *Pseudotsuga menziesii* / *Muhlenbergia montana* Forest association.

The map class Douglas-fir Forest occurs only at high elevation on Darton Dome and O'Leary Peak, mostly with eastern or northern aspects. Douglas-fir Forest does not occur in Sunset Crater Volcano NM and only occurs in the park environs; the total area mapped in the park environs is 29 hectares within 7 polygons.

COMMENTS

Sunset Crater Volcano National Monument

This relevé did not represent any previously described associations within the Douglas-fir Forest alliance. Therefore, it was placed at the courser level of classification in the Douglas-fir Forest alliance. The vegetation assemblage may represent a new association, but such designation will require additional relevé data from other locations.

Global Comments

This alliance is derived from a series concept, where the presence of *Pseudotsuga menziesii* is diagnostic if other more shade-tolerant conifers are absent (presumes dominance of *Pseudotsuga menziesii* if some form of disturbance or extreme edaphic conditions do not limit its regeneration). In the Pacific ranges, the dominant taxon is *Pseudotsuga menziesii* var. *menziesii*, while *Pseudotsuga menziesii* var. *glauca* is the dominant in forests of the Rocky Mountains south into Mexico.

Global Dynamics

Successional relationships in this alliance are complex. *Pseudotsuga menziesii* is less shade-tolerant than many northern or montane trees such as *Tsuga heterophylla*, *Abies concolor*, *Picea engelmannii*, or *Thuja plicata*, and seedlings compete poorly in deep shade. At drier locales, seedlings may be favored by moderate shading, such as by a canopy of *Pinus ponderosa*, which helps to minimize drought stress. In some locations, much of these forests have been logged or burned during European settlement, and present-day stands are second-growth forests dating from fire, logging, or other stand replacing disturbances (Mauk and Henderson 1984, Chappell et al. 1997). *Pseudotsuga menziesii* forests were probably subject to a moderate severity fire regime in pre-settlement times, with fire-return intervals of 30-100 years. Many of the important tree species in these forests are fire-adapted (*Populus tremuloides*, *Pinus ponderosa*, *Pinus contorta*, *Larix occidentalis*) (Pfister et al. 1977), and fire-induced reproduction of *Pinus ponderosa* can result in its continued codominance in *Pseudotsuga menziesii* forests (Steele et al. 1981). Seeds of the shrub *Ceanothus velutinus* can remain dormant in forest stands for 200 years (Steele et al. 1981) and germinate abundantly after fire, competitively suppressing conifer seedlings. Some stands may have higher tree-stem density now than historically, due largely to fire suppression. Fire suppression has also lead to the succession of *Pinus ponderosa* woodlands or *Quercus* spp. woodlands to *Pseudotsuga menziesii* forests.

RANGE

Sunset Crater Volcano National Monument

The Douglas-fir / Mountain Muhly Forest occurs on higher elevation cinder cones in the project environs. Only one relevé was sampled, at the top of Darton Dome.

Globally

This forest association occurs on mountains and plateaus in Trans-Pecos Texas, New Mexico, Arizona, and possibly Colorado.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

This association occurs on the northern and eastern slopes of cinder cones in cinder gravel within the project environs at high elevations. The one relevé sampled occurred at an elevation of 2,250m and in a flat location (~8% slope).

Globally

This forested plant association occurs on mountains and plateaus in Trans-Pecos Texas, New Mexico, Arizona, and possibly Colorado. Sites are variable and include rocky ridge tops, gentle to steep slopes, stream sides and cinder cones. Elevation ranges from 2,650–2,970 m (8,700–9,750 feet) on steep south and west facing slopes, and down to 2245 m (7500 feet) on cool, northerly slopes. Substrates are generally dry, shallow, well-drained, gravelly or cobbly, coarse-textured soils. Lower elevation soils may be deep sands or cinder.

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

In the one relevé of Douglas-fir / Mountain Muhly Forest sampled total vegetation cover was 50%, with 45% relative cover in the tree layer, 1% in the shrub layer, and 13% in the ground layer. Ten species were recorded.

Pseudotsuga menziesii and *Pinus ponderosa* were the dominant trees with *Pseudotsuga menziesii* having 25% cover and *Pinus ponderosa* with 20% cover. The DBH for *Pseudotsuga menziesii* ranged from 11-95cm (average 23cm) and the DBH for *Pinus ponderosa*, mostly young trees, ranged from 11.5-21.5cm (average 14.5). Tree heights ranged from 3-20 m.

The shrub layer was virtually absent (<0.5%). The herbaceous layer was characterized by *Muhlenbergia montana* (12% cover).

Globally

This plant association is characterized by a moderately dense evergreen tree canopy dominated or co-dominated by *Pseudotsuga menziesii* with a *Muhlenbergia montana* dominated graminoid layer. Other tree species may include large *Pinus ponderosa* (often co-dominant), and scattered *Pinus flexilis* (northern stands), *Pinus strobiformis*, *Pinus edulis*, *Juniperus deppeana* or, *J. scopulorum* (especially on dryer sites and southern stands). *Abies concolor* is not present or accidental. *Quercus gambelii* may be present in the subcanopy (tree form) or tall-shrub layer, but with less than 5% cover. Shrub cover is typically sparse (< 10% cover) and consists of scattered *Ceanothus fendleri*, *Cercocarpus montanus*, *Holodiscus dumosus*, *Mahonia repens*, *Quercus grisea* or *Ribes cereum*. The herbaceous layer is dominated by graminoids and is moderately dense and diverse. *Muhlenbergia montana* is the most consistent graminoid species and typically dominates. Other graminoids include *Blepharoneuron tricholepis*, *Bromus* spp., *Carex rossii*, *Elymus elymoides*, *Koeleria macrantha*, and *Poa fendleriana* but not *Festuca arizonica* or *Muhlenbergia virescens*. The forb cover is sparse. Common species are *Artemisia ludoviciana*, *Geranium caespitosum*, *Lithosperma multiflorum*, *Packera neomexicana*, *Pseudocymopterus montanus*, and *Thalictrum fendleri* (Alexander et al. 1987, Fitzhugh et al. 1987, Muldavin et al. 1996, Stuever and Hayden 1997a or b). The graminoid layer has greater than or equal shrub cover.

CONSERVATION RANK G4

DATABASE CODE Cegl000443

MAP CLASSES

Douglas-fir / Mountain Muhly Forest association was mapped as map class Douglas-fir Forest corresponding to map code 21. The map class Douglas-fir Forest includes both the *Pseudotsuga menziesii* Forest Alliance and *Pseudotsuga menziesii* / *Muhlenbergia montana* Forest association.

This map class only occurs within the environs of the study boundary and does not occur within Sunset Crater Volcano NM. Map class Douglas-fir Forest occurs on the northern side of Darton Dome and along the southeastern side of O'Leary Peak. The total hectares mapped are 29 and these occur within 7 polygons.

COMMENTS

Sunset Crater Volcano National Monument

The Douglas-fir / Mountain Muhly Forest association differs from the global description due to having <60% tree cover and with *Pinus ponderosa* co-dominating the association. This association needs to be further sampled within the Colorado Plateau to determine if this relevé would be better classified as a woodland rather than a forest type. Due to this type occurring in the environs of the project boundary, additional relevés were not sampled within this project boundary.

Global Comments

Two phases of this association are described by Stuever and Hayden (1997a or b). The limber pine (*Pinus flexilis*) phase is described from higher elevation stands in northern New Mexico (Muldavin et al. 1996) and the two-needle pinyon (*Pinus edulis*) phase from more southern latitudes where *Pinus edulis*, *P. strobiformis*, *Juniperus deppeana*, and *J. scopulorum* are common seral species (Stuever and Hayden 1997a or b).

Global Dynamics

Both diagnostic species are tolerant of ground fire. *Pseudotsuga menziesii* develops thick fire-resistant bark with age, and *Muhlenbergia montana* resprouts after burning although it may take a few years to recover to pre-burn density (Fischer and Bradley 1987, Wright et al. 1979). Fire-return interval can be low in areas in dry, rocky stands where ground fire is limited by lack of continuous fine fuels. The sparse shrub layer reduces the risk of crown fire by limited ladder fuel to the crown of overstory trees. If fire frequency is high, the more fire-resistant tree *Pinus ponderosa* will be favored and may become dominant (Stuever and Hayden 1997b). Disturbance of tree canopy favors graminoids (Alexander et al. 1987). Improper livestock grazing (where accessible) can result in converting the herbaceous layer from graminoids to unpalatable forbs (Fitzhugh et al. 1987). Drier sites tend to have more graminoids and more mesic stands have more shrubs (Alexander et al. 1987).

RANGE

Sunset Crater Volcano National Monument

Two-needle Pinyon - Utah Juniper / Blue Grama Woodland occurs within Sunset Crater Volcano NM on the eastern side of Sunset Crater. This association is also common within the environs at the bases of cinder cones. This association is found on Black Mountain, Darton Dome, O' Leary Peak, Robinson Mountain, and Robinson Crater in the study environs.

Globally

This woodland association occurs in the cinder fields, mountains and mesas in the southern Colorado Plateau and Mogollon Rim, and may extend into southern Utah and western Colorado.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

This association occurs at 2,100-2,300m. It occurs at the base of cinder cones and in flat lower elevation areas. It is frequently on the southern exposure of cinder cones and occasionally climbs towards the top of the cinder cones. Slope ranges from 10-40%. The typical substrate consists of cinder gravel with a smaller percentage of cinder sand and lava cobbles.

Globally

This woodland association is known from the mountains and mesas in the southern Colorado Plateau, Mogollon Rim and extends into southern Utah and western Colorado. Elevations normally range from 2,100-2,300m (6,885-7,540 feet). Sites are variable, but generally are relatively dry and rocky. Stands occur on flat to moderate slopes along drainages and on mesa tops, on gentle to moderate 10-40% rocky slopes of foothills, and at the base of cinder cones. The substrates are variable and range from deep, coarse textured soil derived from cinder, to sandy loams derived from sandstone or fine-textured soils derived from limestone.

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Two-needle Pinyon - Utah Juniper / Blue Grama Woodland was sampled in seven relevés with a total vegetation cover ranging from 23-62% (average 42%). Absolute cover in the tree layer ranges from 20-55% (average 30%), in the shrub layer 2-10% (average 5%), and in the herbaceous layer 2-20% (average 5%). The total number of species ranged from 12-29 species (average 21).

Within the tree layer *Pinus edulis* ranged from 11-54% absolute cover (average 19%) and *Juniperus osteosperma* 2-26% (average 9%). *Juniperus deppeana* occurred in 43% of the total relevés with 6-16.5% absolute cover (average 11%). *Pinus edulis* DBH ranged from 11-92cm (average 29cm), *Juniperus osteosperma* 11.5-59.5cm (average 26cm), and *Juniperus deppeana* 10.5-75cm (average 32cm). One to five percent of all trees within this association had a height of 3-5 m, 5-10% were 5-10 m, and less than 1% were 10-20m tall.

The shrub layer had 2-10% absolute cover with the dominant shrubs consisting of *Fallugia paradoxa* and *Rhus trilobata*. The herbaceous layer had 2-20% absolute cover with the characteristic species being *Bouteloua gracilis* and *Artemisia dracunculus*.

Globally

This plant association is characterized by an open to moderately dense tree canopy (10-65% cover) co-dominated by *Pinus edulis* and *Juniperus osteosperma*. *Pinus edulis* may be present with relatively small cover in some stands. *Juniperus deppeana* may replace *Juniperus osteosperma* in southern stands. Other species of *Juniperus* such as *J. scopulorum* may be present in higher elevation stands. Shrub cover is sparse (<10% cover). If *Quercus gambelii* is present, it has less than 5% cover. Other associated shrubs may be present such as scattered *Brickellia californica*, *Cercocarpus montanus*, *Ericameria nauseosa*, *Eriogonum corymbosum*, *Fallugia paradoxa*, *Gutierrezia sarothrae*, *Opuntia* spp., *Purshia stansburiana*, *Rhus trilobata*, *Ribes cereum* or *Yucca* spp. The herbaceous layer is typically moderately dense and is dominated by the warm-season, perennial short grass, *Bouteloua gracilis*. Associated graminoids include *Aristida* spp., *Achnatherum hymenoides* (= *Oryzopsis hymenoides*), *Bouteloua curtipendula*, *Elymus elymoides*, *Koeleria macrantha*, *Hesperostipa comata* (= *Stipa comata*), *H. neomexicana* (= *Stipa neomexicana*), and *Pleuraphis jamesii* (= *Hilaria jamesii*). *Muhlenbergia montana* is absent or scarce (<1% cover). Forb cover is typically low, but may be moderately diverse. Species such as *Artemisia dracunculus*, *Eriogonum* spp., and *Oxytropis lambertii* are common.

CONSERVATION RANK G5

DATABASE CODE Cegl000778

MAP CLASSES

Two-needle Pinyon - Utah Juniper / Blue Grama Woodland corresponds to the map class Pinyon Pine –Utah Juniper / Blue Grama Woodland (map code 11) and vegetation cover modifier Pinyon Pine – Utah Juniper / Blue Grama Woodland (Sparse) (map code 12). The sparse modifier refers to association occurrences with less than 25% trees and greater than 15% herbaceous cover. Map class Pinyon Pine –Utah Juniper / Blue Grama Woodland includes the Pinyon Pine –Utah Juniper / Blue Grama Woodland association and the Two-needle Pinyon / Sparse Understory Forest association.

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

Pinyon Pine –Utah Juniper / Blue Grama Woodland occurs primarily within the environs of the study boundary and does not occur on Sunset Crater. It occurs mainly on the northern and eastern section of the project boundary. The total area mapped for map class 11 within Sunset Crater Volcano NM is 2 hectares within 5 polygons and the total area in the park environs is 361 hectares within 51 polygons. Map code 12 does not occur within Sunset Crater Volcano NM; however, the total area in the park environs is 33 hectares within 8 polygons.

COMMENTS

Sunset Crater Volcano National Monument

Two-needle Pinyon - Utah Juniper / Blue Grama Woodland association may have a sparse understory layer or be dominated by herbaceous species other than *Bouteloua gracilis*. If *Bouteloua gracilis* is present it is an indicator species for this association as currently classified. Further sampling within the Colorado Plateau is needed to determine if *Bouteloua gracilis* is a true indicator for this association.

Global Comments

The two *Pinus edulis* / *Bouteloua gracilis* plant associations are treated as phases in Stuever and Hayden (1997a). In the NVCS we are including stands with southern Great Plains, Chihuahua Desert floristic affinities in the *Pinus edulis* – (*Juniperus monosperma*) / *Bouteloua gracilis* Woodland (CEGL002151) and stands with the Colorado Plateau and Great Basin floristic affinities in the *Pinus edulis* – (*Juniperus osteosperma*) / *Bouteloua gracilis* Woodland (CEGL000778). Both of these associations may include stands codominated by *Juniperus deppeana* in their southern extent. Stuever and Hayden (1997a) also described *Juniperus deppeana* phase (recognized by its dominance in the stand) and hillslope phase, which occurs on slopes > 15% and may have low cover of grasses (<5% cover). More survey is needed to fully understand the distribution and ecological relationships between these 3 species of *Juniperus* and *Pinus edulis*.

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

This alliance is found at high elevations on O’Leary Peak in the project environs.

Globally

Stands included in this widespread woodland alliance occur intermittently throughout the Rocky Mountains and on mountains and plateaus in the Great Basin and Colorado Plateau, and on breaks in the northwestern Great Plains. The alliance ranges from Montana to New Mexico and from western North Dakota to southern California. It also likely occurs in southern Alberta and southeastern British Columbia, Canada.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

The one relevé sampled was found at an elevation of 2,725m on the southeastern side of O’Leary peak on a steep slope of 40%. The substrate was mainly cinder gravel and basaltic derived soils.

Globally

Woodlands included in this alliance occur intermittently from timberline to lower montane and foothill zones throughout much of the Rocky Mountains, on escarpments and other geographic breaks in the northwestern Great Plains, and in mountains in the Great Basin and southern California. Elevations range from 850-3500 m. Climate is semiarid, cold temperate. Annual precipitation patterns and amounts are variable, but locally the sites are typically xeric on exposed, windswept rocky slopes and ridges from subalpine to foothills and prairie breaks. Some stands are on eroded substrates and resemble 'badlands' while others may occur on lava flows. These open woodlands occur on all aspects, but are most common on dry south- and west-facing slopes. Soils are typically shallow, skeletal and coarse-textured such as gravelly, sandy loams or loams, but may include alkaline clays. Stands grow best on calcareous soils derived from limestone or sandstone, but parent material is variable and includes a variety of igneous, sedimentary, and metamorphic rocks. Depending on the stand, bedrock may include a mixture of andesite, basalt, cinder, lava, limestone, dolomite, granite, gneiss, quartzite, rhyolite, schist, sandstone, serpentine, or shale. Exposed bedrock is common and many stands have over 50% bare soil. Soil pH is typically neutral or slightly alkaline, but can range from acid to alkaline.

Adjacent vegetation at high elevations includes alpine meadows and shrublands and subalpine forests dominated by *Picea*, *Abies* or *Pseudotsuga*. Adjacent montane stands are dominated by *Pinus ponderosa*, *Pinus contorta* or *Pseudotsuga menziesii*. At lower elevations adjacent vegetation may include *Juniperus*-dominated woodland and savannas; shrublands dominated by species of *Artemisia*, *Cercocarpus*, or *Purshia tridentata*; dry prairie; or riparian woodland dominated by *Pseudotsuga menziesii*. The transition can be abrupt or an extended ecotone where the woodlands grade into a savanna.

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

The one Limber Pine Woodland relevé had a total vegetation cover of 40%, with 35% absolute cover in the tree layer, 2% in the shrub layer, and 5% in the herbaceous layer. Sixteen species occurred in this relevé.

The dominant species within the tree layer were *Pinus flexilis* (12% absolute cover), *Pseudotsuga menziesii* (8% absolute cover), and *Populus tremuloides* (7% absolute cover). The DBH for *Pinus flexilis* ranged from 13-19cm (average 15cm), *Pseudotsuga menziesii* ranged from 30-93cm (average 36cm), and *Populus tremuloides* ranged from 13-77.6cm (average 59cm). Tree height was distributed between 3-20m.

The shrub and herbaceous layer were sparse (7% absolute cover) with the dominant species being *Brickellia californica*, *Holodiscus dumosus*, and *Ribes cereum*.

Globally

Stands included in this widespread woodland alliance occur locally on warm, dry, rocky, exposed sites in the Rocky Mountain west, northwestern Great Plains, and desert mountains in the Great Basin and in southern and eastern California. Stands have an open canopy typically 3-10 m tall, but individuals may reach 15 m. The stands are solely dominated or codominated by the evergreen needle-leaved tree *Pinus flexilis*. Other trees species that may be present to codominant vary by geography and elevation zones throughout the woodland's range. In the subalpine, *Pinus albicaulis*, *Picea engelmannii* or *Pseudotsuga menziesii* may be present. In the montane zone, *Pinus contorta*, *Pinus ponderosa* or *Pseudotsuga menziesii* are frequently present, and in the lower montane transition zone from woodlands to grasslands or shrublands, *Juniperus osteosperma* or *Juniperus scopulorum* may co-occur with *Pinus flexilis*. In California, associates may include *Abies concolor*, *Pinus albicaulis*, *Pinus balfouriana*, *Pinus contorta*, *Pinus jeffreyi*, and *Pinus longaeva* (Sawyer and Keeler-Wolf 1995).

The understory vegetation is typically sparse because sites are dry and have a large cover of rock. On stands occurring in the breaks in the plains, Johnston (1987) reported 18% exposed rock and 25% bare soil. A sparse shrub layer may be present. The taller shrubs may include *Artemisia tridentata*, *Cercocarpus ledifolius*, *Jamesia americana*, *Rhus trilobata*, *Shepherdia canadensis*, *Symphoricarpos oreophilus* and immature tree species. The most frequent low shrubs are *Arctostaphylos uva-ursi*, *Artemisia arbuscula*, *Artemisia nova*, *Juniperus communis*, *Mahonia repens*, *Purshia tridentata*, and *Yucca glauca*. The herbaceous layer often dominates the understory. The most common species are graminoids such as *Bouteloua gracilis*, *Calamagrostis purpurascens*, *Carex rossii*, *Festuca idahoensis*, *Festuca campestris*, *Leucopoa kingii* (= *Festuca kingii*), *Koeleria macrantha*, *Achnatherum hymenoides* (= *Oryzopsis hymenoides*), and *Pseudoroegneria spicata*. Scattered forbs may include species of *Achillea*, *Antennaria*, *Arenaria*, *Arnica*, *Astragalus*, *Erigeron*, *Eriogonum*, *Hymenopappus*, *Hymenoxys*, *Liatris*,

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

Sedum, *Solidago*, and *Thermopsis*. In six relevés in the Little Missouri National Grassland in western North Dakota, the average cover for each of the strata was trees 38%, shrubs 21%, graminoids 20%, and forbs 9% (USFS 1992).

DATABASE CODE A.540

MAP CLASSES

Limber Pine Woodland Alliance is mapped as map class Limber Pine Woodland, map code 13.

Limber Pine Woodland Alliance occurs only in the environs of the study boundary on O'Leary Peak. The total area mapped within the park environs is 13 hectares within 9 polygons.

COMMENTS

Sunset Crater Volcano National Monument

The one relevé sampled did not represent any of the previously described associations within the Limber Pine Woodland alliance. In order to classify this relevé it was placed at a coarser classification level within the Limber Pine Woodland alliance. This relevé may represent a new vegetation association, however sampling at additional locations is needed to verify this.

Global Comments

It may be difficult to determine which tree species are dominant in a mixed, montane or subalpine forest stand, especially when *Pinus flexilis* is seral on *Pseudotsuga menziesii* habitat type sites. Some stands included in this alliance are too sparse to be classified as woodlands, especially those growing on lava (Eggler 1941).

Global Dynamics

Although some of the conifers that are typically codominant in *Pinus flexilis* stands are late successional species, they are not likely to displace *Pinus flexilis*. This is because most of these stands occur on harsh sites where *Pinus flexilis* is more competitive than most other conifer species. These stands are generally considered to be topographic or edaphic 'climax' stands (Cooper 1975, Eyre 1980). Even in stands at lower elevations, such as prairie breaks, it is unlikely that other coniferous species will become dominant (Eyre 1980). Because *Pinus flexilis* occurs over a broad range of elevations, it can also be important as a post-fire seral species on drier sites in the Rocky Mountains (Cooper 1975, Peet 1988). Peet (1978) reported apparent competitive displacement with *Pinus flexilis* in Colorado. He noted that *Pinus flexilis* may dominate xeric sites from low to high elevations, except where *Pinus aristata* or *Pinus albicaulis* occur. There, *Pinus flexilis* is largely restricted to lower elevation, rocky sites. Peet (1978) also reported that *Pinus flexilis* occurs in the less xeric *Pinus contorta* and *Pinus ponderosa* habitats.

Birds and small mammals often eat and cache the large, wingless pine seeds. Most important is the Clark's nutcracker, which can transport the seeds long distances and cache them on exposed windswept sites (Lanner and Vander Wall 1980). This results in the regeneration of pines in clumps from forgotten caches (Eyre 1980, Steele et al. 1983).

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Ponderosa Pine / Blue Grama Woodland commonly occurs in the park environs and in the southeast corner of Sunset Crater Volcano NM. It is commonly found in the flat areas adjacent to Hwy 89 and FS road 776. It is also located at the base of cinder cones including Darton Dome, Robinson Mountain, and O'Leary Peak.

Globally

This ponderosa pine woodland occurs in the southern Rocky Mountains, extending east on southern Great Plains escarpments as far as Oklahoma, south to the mountains of West Texas, west to the Colorado Plateau and Mogollon Rim of New Mexico, Arizona, and southern Utah.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

This association's elevation ranged from 2,050-2,250m (average 2,120m) and the slope ranged from 4-25% (average 12%).

Globally

This widespread woodland occurs at foothill and lower montane elevations from the southern Rocky Mountains, extending east on southern Great Plains escarpments, south to the mountains of West Texas, west to the Colorado Plateau and Mogollon Rim of New Mexico, Arizona and Utah. Elevation ranges from 1,740-2,610 m (5,700-8,550). Sites occur on dry, gentle to steep slopes on all aspects, but are more common on southern and western aspects, especially at higher elevations. Substrates are quite variable and include shallow sandy loam soils derive from granitic parent materials, coarse cinder soils and clayey soil with or without high coarse fragment content.

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

The Ponderosa Pine / Blue Grama Woodland has a total vegetation cover that ranges from 40-75% absolute cover (average 61%). The average cover for the tree layer ranged from 5-30% (average 15%), shrub layer 2-25% (average 8%), and herbaceous layer 30-50% (average 39%). Species richness ranged from 15-39 (average 24) in the three relevés measured.

The tree layer is dominated by *Pinus ponderosa*, with DBH ranging from 16-58cm (average 30cm). The shrub layer was often characterized by *Ericameria nauseosa* (1-35% absolute cover). The herbaceous layer is dominated by *Bouteloua gracilis* with 3-25% absolute cover (average 20%).

Globally

This plant association is characterized by an open to moderately dense, evergreen, needleleaf tree canopy 10-30 m tall that is either dominated by *Pinus ponderosa* or codominated by *Pinus ponderosa* and *Pinus edulis*. *Juniperus monosperma*, *J. osteosperma*, *J. deppeana* or *J. scopulorum* may be important subdominants. The typically moderately dense herbaceous layer has greater cover than the shrub layer, and is dominated by graminoids. *Bouteloua gracilis*, the warm-season, sod-forming, shortgrass dominates the herbaceous layer. Common graminoid associates include *Aristida* spp., *Bouteloua hirsuta*, *Carex geophila*, *Elymus elymoides*, *Hesperostipa comata*, *Koeleria macrantha*, *Muhlenbergia montana*, *Poa fendleriana*, or *Schizachyrium scoparium*. *Muhlenbergia montana* may be present, but only with low cover (<2%) and does not co-dominate. *Quercus gambelii* may be present in the sparse shrub layer (<10% cover) with low cover (<5%). Other shrubs may include scattered *Artemisia tridentata*, *Ceanothus fendleri*, *Cercocarpus montanus*, *Chrysothamnus viscidiflorus*, *Ericameria nauseosa*, *Fallugia paradoxa*, *Purshia tridentata*, *Quercus grisea*, *Rhus trilobata*, and *Tetradymia canescens*. Forb cover is typically sparse and may include species such as *Antennaria* spp., *Artemisia ludoviciana*, *Erigeron* spp., *Eriogonum racemosum*, *Chaetopappa ericoides*, *Packera neomexicana*, and *Penstemon* spp.

CONSERVATION RANK G4

DATABASE CODE Cegl000848

MAP CLASSES

The association Ponderosa Pine / Blue Grama Woodland is represented by map class Ponderosa Pine / Montane Grass Mosaic (map code 15). Ponderosa Pine / Montane Grass Mosaic is a combined map class of Ponderosa Pine / Blue Grama Woodland and Ponderosa Pine / Mountain Muhly Woodland. These two associations were combined in one map class due to difficulties in photointerpreting the different grass understories under ponderosa pine canopy cover.

Ponderosa Pine / Montane Grass Mosaic is mapped as the dominant map class in the western section of the project boundary. This map class also occurs in a small patch on Darton Dome and in the southeastern section on Forest Service lands. The total area mapped in Sunset Crater Volcano NM is 3 hectares within 1 polygon and in the park environs 1223 hectares within 69 map polygons.

COMMENTS

Sunset Crater Volcano National Monument

This association has high variability in the shrub, tree, and herbaceous layer. With more relevés collected within the Colorado Plateau this association may be subdivided into additional associations.

Global Comments

This ponderosa pine woodland is a broadly defined plant association. Stuever and Hayden (1997b) report 6 phases: the *Bouteloua gracilis*, *Schizachyrium scoparium*, *Andropogon hallii*, *Artemisia tridentata*, *Quercus grisea*, and *Q. gambelii* phases. Hanks et al. 1983 described 4 phase of the *Pinus ponderosa*/*Bouteloua gracilis* Habitat Type from northern Arizona. More classification review is needed to further define the relationships between these phases and other similar plant associations. Alexander et al. (1987), DeVelice et al. (1986), and Muldavin et al. (1996) also described phases of this Habitat Type that need further review and cross-walking to NVCS. Youngblood and Mauk (1985) included stands of this association in their broadly defined *Pinus ponderosa*/*Muhlenbergia montana* Habitat Type.

Global Dynamics

Both diagnostic species are tolerant of ground fire. *Pinus ponderosa* develops thick fire-resistant bark that protects it from ground fires (Bradley et al. 1992). *Bouteloua gracilis* resprouts after burning and is unharmed by fires in years with above normal winter and spring precipitation, but can be severely damaged during drought years (Wright and Bailey 1980). Most *Pinus ponderosa* stands have relatively frequent fires (every 3-20 years), but fire are less frequent in dry, rocky stands where ground fire is limited by lack of continuous fine fuels (Stuever and Hayden 1997b). Fire-return interval has generally increased because of active fire suppression and historic livestock grazing, which has reduced the fine-fuels needed to carry ground fires (Madany and West 1980, Savage and Swetnam 1990). Absence of fire has led to large accumulations of ground fuel and has likely resulted in denser stands and invasion of less fire-adapted, shade tolerant species species such as *Pseudotsuga menziesii*. This has likely increased risk of severe, stand replacing crown fires.

Sunset Crater Volcano National Monument

Ponderosa Pine / Mountain Muhly Woodland occurs frequently in the park environs around Sunset Crater Volcano NM. It occurs most frequently in the northwestern section of the environs around Robinson Crater, Robinson Mountain, and O'Leary Peak. Also in the environs it occurs south of Bonito Park at the base of unnamed cinder cones.

Globally

This widespread woodland occurs at foothill and lower montane elevations in the southern Rocky Mountains, extending south to the mountains of West Texas, and west to the Mogollon Rim and Colorado Plateau of New Mexico, Arizona and Utah.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

Ponderosa Pine / Mountain Muhly Woodlands occurs between an elevational range of 2,150-2,270m (average 2,200m). Slope is low to moderate and ranges from 1-35% (average 9%). Typically it is on cinder gravel.

Globally

This widespread woodland occurs at foothill and lower montane elevations in the southern Rocky Mountains, extending south to the mountains of West Texas, and west to the Mogollon Rim and Colorado Plateau. Elevation ranges from 2,150-2,870 m (7,050-9,400 feet). Stands occur on bottomlands, elevated plains, cinder cones, piedmont slopes, mesas, foothills, and mountains. Sites include gentle to steep slopes on all aspects, but are more common on southern and western aspects, especially at higher elevations. Substrates are variable, but are typically shallow, rocky, coarse-textured soils derived from granitic or cinder parent materials. There is considerable cover of bare soil and exposed bedrock.

Globally

Pinus edulis, *Pinus discolor*, *Juniperus monosperma*, *J. osteosperma*, *J. deppeana*, *J. scopulorum*, *Artemisia tridentata*, *Brickellia californica*, *Ceanothus fendleri*, *Cercocarpus montanus*, *Chrysothamnus viscidiflorus*, *Ericameria nauseosa*, *Fallugia paradoxa*, *Quercus gambelii*, *Purshia tridentata*, *Quercus grisea*, *Rhus trilobata*, *Tetradymia canescens*, *Yucca baccata*, *Blepharoneuron tricholepis*, *Bouteloua gracilis*, *Carex geophila*, *C. rossii*, *Elymus elymoides*, *Koeleria macrantha*, *Poa fendleriana*, *Schizachyrium scoparium*, *Artemisia ludoviciana*, *Eriogonum racemosum*, *Chaetopappa ericoides*, *Lotus wrightii*, *Oxytropis lambertii*, *Packera neomexicana*

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

The total vegetation cover ranged from 22-50% (average 37%). The tree layer absolute cover ranged from 12-35% (average 22%), shrub layer ranged 0-9% (average 2%), and the herbaceous strata ranged from 7-35% (average 16%). The total species richness ranged from 12-37 species (average 24) as found on 12 relevés.

The tree layer was dominated by *Pinus ponderosa* with cover ranging from 5-36% (average 33%). DBH ranged from 11-99cm (average 31cm) and tree height ranged from 5-20m. The herbaceous layer was dominated by *Muhlenbergia montana* with 2-20% cover (average 9%). The shrub layer was sparse.

Globally

This association is characterized by an open to moderately dense, evergreen, needleleaf tree canopy to 10-30 m tall that is dominated or codominated by *Pinus ponderosa*. Associated tree species vary geographically. *Pinus edulis*, *Pinus discolor*, *Juniperus monosperma*, *J. osteosperma*, *J. deppeana* and *J. scopulorum* may be important in the tree canopy. *Pseudotsuga menziesii*, *Pinus flexilis*, and *Populus tremuloides* may also be present, but are considered accidental. The typically moderately dense herbaceous layer has greater cover than the shrub layer, and is dominated by graminoids. *Muhlenbergia montana*, a warm-season, medium-tall perennial typically dominates the herbaceous layer and is diagnostic of this association. *Bouteloua gracilis* may co-dominate. Common graminoid associates include *Aristida* spp., *Blepharoneuron tricholepis*, *Carex geophila*, *C. rossii*, *Elymus elymoides*, *Koeleria macrantha*, *Poa fendleriana* and *Schizachyrium scoparium*. *Festuca arizonica*, *Muhlenbergia virescens*, *M. dubia*, *M. emersleyi* and *Hesperostipa* spp. are typically absent. *Quercus gambelii* may be present with low cover (to 5%) in the sparse shrub layer (<10% cover). Other scattered shrubs may include *Artemisia tridentata*, *Brickellia californica*, *Ceanothus fendleri*, *Cercocarpus montanus*, *Chrysothamnus viscidiflorus*, *Ericameria nauseosa*, *Fallugia paradoxa*, *Mahonia* spp., *Purshia tridentata*, *Quercus grisea*, *Rhus trilobata*, *Tetradymia canescens* or *Yucca baccata*. Forb cover is typically sparse and may include species such as *Antennaria* spp., *Artemisia ludoviciana*, *Erigeron* spp., *Eriogonum racemosa*, *Chaetopappa ericoides*, *Lotus wrightii*, *Oxytropis lambertii*, *Packera neomexicana*, and *Penstemon* spp.

MAP CLASSES

The association Ponderosa Pine / Mountain Muhly Woodland is represented by Ponderosa Pine / Montane Grass Mosaic (map code 15). Ponderosa Pine / Montane Grass Mosaic is a combined map class of Ponderosa Pine / Blue Grama Woodland and Ponderosa Pine / Mountain Muhly Woodland. These two associations were combined in one map class due to difficulties in photointerpreting the different grass understories under ponderosa pine canopy cover.

Ponderosa Pine / Montane Grass Mosaic is mapped as the dominant map class in the western section of the project boundary. This map class also occurs in a small patch on Darton Dome and in the southeastern section on Forest

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

Service lands. The total area mapped in Sunset Crater Volcano NM is 3 hectares within 1 polygon and in the park environs 1223 hectares within 69 map polygons.

COMMENTS

Global Comments

This ponderosa pine woodland is a broadly defined plant association. Stuever and Hayden (1997b) suggested the xeric upland and mesic bottomland stands be put into different phases. Fitzhugh et al. (1987) suggested it be divided into regional phases.

Global Dynamics

Both diagnostic species are tolerant of ground fire. *Pinus ponderosa* develops thick fire-resistant bark and *Muhlenbergia montana* resprouts after burning, although it may take a few years to recover to pre-burn density (Fischer and Bradley 1987, Bradley et al. 1992). This association had frequent fires (every 3-10 years on average) in pre-settlement times, but fires are less frequent in dry, rocky stands where ground fire is limited by lack of continuous fine fuels (Stuever and Hayden 1997a or b). Fire-return interval has generally increased because of active fire suppression and historic livestock grazing, which has reduced the fine-fuels needed to carry ground fires (Madany and West 1980, Savage and Swetnam 1990). Absence of fire has led to large accumulations of ground fuel and has likely resulted in denser stands and invasion of less fire-adapted, shade tolerant species such as *Pseudotsuga menziesii*. This has likely increased risk of stand replacing crown fires

Improper livestock grazing will favor the more grazing-tolerant species such as *Bouteloua gracilis*, and over time can may eliminate *Muhlenbergia montana* and convert the stand into a *Pinus ponderosa* / *Bouteloua gracilis* Woodland (CEGL000848).

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Ponderosa Pine / Cinder Woodland is one of the most common associations in the mapping project and is found on level and on steep slopped cinder. Within Sunset Crater Volcano NM it occurs in lower elevations on the north side of Sunset Crater. It predominates the central area of the park environs and occurs on O'Leary peak and in the surrounding lower elevation areas.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

Ponderosa Pine / Cinder Woodlands elevation ranges from 2,020-2,300m (average 2,060m). The association occurs on steep slopes on cinder cones and flatter areas (0-45% slope, average 14%).

MOST ABUNDANT SPECIES

Sunset Crater Volcano National Monument

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

The total vegetation cover ranged from 21-70% (average 36%). The tree layer absolute cover ranged from 19-55% (average 32%), the shrub layer 0.5-10% (average 3%), and the herbaceous strata 0.5-20% (average 3%). The total species richness ranged from 5-20 species (average 11) as measured on 22 relevés.

The tree layer was dominated by *Pinus ponderosa* (15-56% absolute cover, average 33%). DBH ranged from 11-99cm (average 31cm) with heights ranging 5-30m. The shrub layer was sparse and the herbaceous cover was low to sparse.

CONSERVATION RANK G?

DATABASE CODE Cegl002998

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

MAP CLASSES

The map class Ponderosa Pine / Cinder Woodland is mapped as Ponderosa Pine / Cinder Woodland and occurs as map code 14.

Ponderosa Pine / Cinder Woodland is mapped as a predominant map class in the central part of the project boundary. In Sunset Crater Volcano NM 93 hectares were mapped within 26 polygons; in the park environs 1038 hectares within 61 polygons.

COMMENTS

Sunset Crater Volcano National Monument

Ponderosa Pine / Cinder Woodland can be distinguished from Ponderosa Pine / Apache Plume Woodland by the understory shrub cover. Ponderosa Pine / Cinder Woodlands shrub layer absolute cover is <5% and Ponderosa Pine / Apache Plume Woodland shrub layer average absolute cover is >5%. This type is similar to *Pinus ponderosa* / *Bouteloua gracilis* Habitat Type, *Andropogon hallii* phase, previously described in Hanks et al. 1983.

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

Populus tremuloides / Cinder Woodland (Local Assemblage)

COMMON NAME Quaking Aspen / Cinder Woodland

CLASSIFICATION CONFIDENCE LEVEL Not Rated, Unique to Monument

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Quaking Aspen / Cinder Woodland is rare within Sunset Crater Volcano NM and in the environs. This association occurs in flat areas as well as on steep cinder slopes. It is found along the edge of the park roadside in the western section of Sunset Crater Volcano NM. It was also found on an unnamed cinder cone east of HWY 89. Only one relevé was sampled of this association and it occurred on the eastern slope of O'Leary Peak.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

The one relevé that was sampled occurred at an elevation of 2,180m. This association can occur on steep slopes and flat areas. The slope of the sampled relevé was steep (68%). It is found on cinder sand and gravel.

MOST ABUNDANT SPECIES

Sunset Crater Volcano National Monument

<u>Stratum</u>	<u>Species</u>
Tree canopy	<i>Populus tremuloides</i>

ASSOCIATED SPECIES

Sunset Crater Volcano National Monument

Holodiscus dumosus, *Juniperus osteosperma*, *Pinus ponderosa*

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Only one relevé was sampled; it had a total vegetation cover of 35% with 29% absolute cover in the tree layer, 6% in the shrub layer, and 4% in the herbaceous layer. Twenty-three species occurred in the relevé.

The tree layer was characterized by *Populus tremuloides* (22% cover). The DBH ranged from 12-71cm (average 22cm). The shrub layer and the herbaceous layer were sparse.

MAP CLASSES

Quaking Aspen / Cinder Woodland was mapped as an inclusion in the surrounding vegetation classes due to mainly occurring in patches less than 0.5 hectares (minimum mapping unit) and being indistinguishable from the surrounding vegetation. However, a separate coverage (sucr_aspen) was developed to illustrate the few patches of this association.

COMMENTS

Sunset Crater Volcano National Monument

Populus tremuloides is a clonal species that grows in the cinder soils and the lava beds within Sunset Crater Volcano NM and in the environs. This species is of particular interest to park staff due to it typically occurring only in mountainous areas (McDougall 1973).

This monument-specific community must be further sampled on the Colorado Plateau to determine if it is unique to Sunset Crater Volcano NM or if it is found across the landscape. Currently it has no global information, conservation rank or database code. Observations and descriptions of additional occurrences are required to confirm it as an association within the NVCS.

ASSOCIATED SPECIES

Sunset Crater Volcano National Monument

Artemisia dracuncululus, *Chamaebatiaria millefolium*, *Echinocereus* sp., *Ericameria nauseosa*, *Penstemon barbatus*, *Pinus edulis*, *Populus tremuloides*, *Ribes cereum*, *Verbascum thapsus*

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Apache Plume - Tasselflower Brickellbush – (Ocean Spray Scree) Scree Shrubland had a total vegetation cover that ranged from 30-50% cover (average 43%). The tree layer was sparse 0-12% (average 4%). The shrub layer was dominant and ranged from 17-45% (average 32%). The herbaceous layer ranged from 3-15% (average 8%). Species richness was 16-24 (average 20%) among the three relevés sampled.

The shrub layer was dominant and consisted of a suite of species including *Holodiscus dumosus* (1-15% absolute cover), *Fallugia paradoxa* (2-17% absolute cover), and *Brickellia grandiflora* (0.5-10% absolute cover). The herbaceous layer was sparse.

MAP CLASSES

The proposed association Apache Plume - Tasselflower Brickellbush – (Ocean Spray Scree) Scree Shrubland is represented by map class Rock Outcrop and Scree Shrubland (Map Code 3). Rock Outcrop and Scree Shrubland combines both Apache Plume - Tasselflower Brickellbush – (Ocean Spray Scree) Scree Shrubland and Rubber Rabbitbrush - Mountain Tail-leaf Rock Outcrop Sparse Vegetation local vegetation assemblages. These two assemblages were combined into one map class due to occurring in very small patches in similar habits throughout the entire project area.

Rock Outcrop and Scree Shrubland was mapped as very small polygons throughout the entire project area. The total area of Rock Outcrop and Scree Shrubland mapped in Sunset Crater Volcano NM is less than 0.5 hectares within 2 polygons and in the park environs is 4 hectares within 11 polygons.

Pinus ponderosa / *Rhus trilobata* Shrubland (Local Assemblage)

COMMON NAME Ponderosa Pine / Three-leaved Sumac Shrubland

CLASSIFICATION CONFIDENCE LEVEL Not Rated, Unique to Monument

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Ponderosa Pine / Three-leaved Sumac occurs on steep cinder slopes. This map class is unique and occurs within the project environs. It occurs on cinder cones east of HWY 89 and east of Lenox Park.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

Only one relevé was sampled within the Ponderosa Pine / Three-leaved Sumac. It occurred at an elevation of 2,200m on steep slopes (27%) and cinder gravel.

MOST ABUNDANT SPECIES

Sunset Crater Volcano National Monument

<u>Stratum</u>	<u>Species</u>
Tree canopy	<i>Pinus ponderosa</i>
Shrub	<i>Rhus trilobata</i>

ASSOCIATED SPECIES

Sunset Crater Volcano National Monument

Artemisia dracunculus, *Ribes cereum*

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Ponderosa Pine / Three-leaved Sumac had a total vegetation cover of 30%. The tree layer absolute cover was 5%, shrub layer 20%, and herbaceous layer 10%. Species richness was 24 species on one relevé.

The tree layer was sparse and consisted of a low cover (5%) of *Pinus ponderosa*. The shrub layer was the dominant layer with 17% cover of *Rhus trilobata*. The herbaceous layer was sparse.

MAP CLASSES

The proposed association Ponderosa Pine / Three-leaved Sumac is mapped as an inclusion of other surrounding map classes. This proposed association occurred mainly in areas less than 0.5 hectares (less than the minimum mapping unit) and therefore was not mapped as a unique map class.

COMMENTS

Sunset Crater Volcano National Monument

This vegetation type is known only from Sunset Crater NM. More inventory is needed to determine if it is more widespread and possibly develop a new NVC association.

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Blue Grama Herbaceous Vegetation had a total vegetation cover ranging from 25-50% (average 42%). Absolute cover in the tree layer ranged from 0-2% (average 0.4%), in the shrub layer 0-6% (average 1.3%), and in the herbaceous layer 25-60% (average 44%). On the 5 relevés sampled species richness ranged from 6-28 species (average 14).

The tree layer was sparse with only an occasional *Pinus ponderosa*. The shrub cover is low/sparse, some relevés have >5% total cover of *Ericameria nauseosa*. The herbaceous layer is the most abundant with the characteristic species being *Bouteloua gracilis*.

Globally

This association is characterized by moderate to dense (25-80% cover) herbaceous layer that is strongly dominated by the warm season, perennial shortgrass, *Bouteloua gracilis*. Associated grasses are *Bouteloua curtipendula*, *Elymus elymoides*, *Muhlenbergia montana*, *M. richardsonis*, *M. torreyi*, *Pascopyrum smithii*, *Pleuraphis jamesii* (= *Hilaria jamesii*), *Sporobolus cryptandrus* and the introduced annual grass *Bromus tectorum*. Forb cover is sparse. Associated forb species include *Artemisia carruthii* and *Artemisia dracunculoides*. Scattered *Ericameria nauseosa* shrubs and an occasional *Juniperus* spp, *Pinus edulis*, or *P. ponderosa* (in montane stands) tree may be present.

CONSERVATION RANK G4Q

DATABASE CODE CEGL001760

MAP CLASSES

Blue Grama Herbaceous Vegetation corresponds to the map classes Montane Grassland (map code 8), Montane Grassland (Rabbitbrush) (map code 9), and Montane Grassland (Bonito Park Historic Agricultural Field) (map code 10). The Rabbitbrush modifier refers to the Blue Grama Herbaceous Vegetation association with >5% total cover of *Ericameria nauseosa*. The Bonito Park Historic Agricultural Field was delineated from aerial photographs as a previous area of agricultural activity. This type was not floristically different from the Blue Grama Herbaceous Vegetation; however, it was evident as an area of past disturbance. Montane Grassland includes both the Blue Grama Herbaceous Vegetation and Mountain Muhly Herbaceous Vegetation associations. These two grasses were combined into one map class, due to often occurring as co-dominates and being indistinguishable from aerial photography.

Montane Grassland occurs mainly in small patches throughout the western half of the project boundary only in the project environs. It was not mapped in Sunset Crater Volcano NM. The total area of Montane Grassland mapped in the park environs is 349 hectares within 156 polygons, this includes 148 hectares and 104 polygons in map code 8, 100 hectares and 51 polygons in map code 9, and 101 hectares and 1 polygon in map code 10.

COMMENTS

Global Comments

This is a low confidence association. There are many other associations in the *Bouteloua gracilis* Herbaceous Alliance (A.1282).

Global Dynamics

Bouteloua gracilis is an extremely drought- and grazing-tolerant shortgrass species. It is one of the most widely distributed grasses in the interior western U.S., and is present in many different grassland, shrubland and woodland communities. It evolved with grazing by large herbivores and generally forms a short sod. However, in some stands ungrazed plants develop the upright physiognomy of a bunchgrass.

FORMATION	Medium-tall bunch temperate or subpolar grassland (V.A.5.N.d.)
ALLIANCE	<i>Muhlenbergia montana</i> Herbaceous Vegetation

CLASSIFICATION CONFIDENCE LEVEL Moderate

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Mountain Muhly Herbaceous Vegetation is a common grassland community that mainly occurs in high elevation mountain meadows. In the environs it occurs mainly in the northwestern section of the environs near Robinson Mountain.

Globally

This plant association forms meadows in the mountains and foothills of Colorado, Arizona and Utah.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

This association is represented by one relevé sampled at an elevation of 2,300m. It was sampled in a small mountain meadow with gentle slope (10%). The soil consisted of cinder sand and gravel.

Globally

This plant association has been described from meadows in the mountains, plateaus and foothills of Colorado, Arizona and Utah. Elevation ranges from 2,300- 2,800 m (7,540-9,200 feet). Sites are typically xeric forest openings or parks in the Ponderosa Pine zone with southern aspects on moderately steep slopes and ridgetops. Occasionally the stands occupy rolling parklands or volcanic cinder fields. The xeric nature of sites appears to be an important environmental factor. Substrates are shallow to moderately deep, rocky, sand to sandy loam textured soils sometimes with a distinct clay horizon. Parent materials are primarily colluvium derived from granite and gneiss or cinder. Bare soil, exposed gravels, and small rocks account for as much as 50% of the ground surface area.

ASSOCIATED SPECIES

Sunset Crater Volcano National Monument

Bromus tectorum, *Ericameria nauseosa*, *Pinus ponderosa*

Globally

Blepharoneuron tricholepis, *Trisetum spicatum*, *Bouteloua curtipendula*, *Bouteloua gracilis*, *Carex duriuscula*, *Danthonia parryi*, *Elymus albicans*, *Festuca brachyphylla*, *Hesperostipa comata*, *Koeleria macrantha*, *Muhlenbergia filiculmis*, *Pascopyrum smithii*, *Poa secunda*, *Schizachyrium scoparium*, *Allium geyeri*, *Antennaria rosea*, *Arenaria fendleri*, *Eriogonum umbellatum*, *Harbouria trachypleura*, *Heterotheca villosa*, *Mertensia lanceolata*, *Opuntia polyacantha*, *Penstemon secundiflorus*, *Phlox diffusa*, *Artemisia frigida*, *Ericameria nauseosa*

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Mountain Muhly Herbaceous Vegetation had a total vegetation cover of 35%. Absolute cover in the tree layer was 4%, 3% in the shrub layer, and 25% in the ground layer. Species richness consisted of 20 species.

Within the tree layer the cover is sparse with an occasional *Pinus ponderosa*. The shrub layer is also sparse with a low cover of *Ericameria nauseosa*. The herbaceous layer was characterized by *Muhlenbergia montana* (15% absolute cover).

Globally

This association is characterized by a moderately dense herbaceous layer that is typically dominated by the warm-season, perennial bunchgrass, *Muhlenbergia montana*, but may be codominated by *Blepharoneuron tricholepis* or *Trisetum spicatum* (= *Trisetum montanum*) (in New Mexico). Other associated graminoids include *Bouteloua curtipendula*, *Bouteloua gracilis*, *Carex duriuscula* (= *Carex eleocharis*), *Danthonia parryi*, *Elymus albicans* (= *Elymus lanceolatus* ssp. *albicans*), *Festuca brachyphylla*, *Hesperostipa comata*, *Koeleria macrantha*, *Muhlenbergia filiculmis*, *Pascopyrum smithii*, *Poa secunda*, and *Schizachyrium scoparium*. The typically sparse forb layer often consists of *Allium geyeri*, *Antennaria rosea*, *Arenaria fendleri*, *Eriogonum umbellatum*, *Harbouria trachypleura*, *Heterotheca villosa*, *Mertensia lanceolata*, *Opuntia polyacantha*, *Penstemon secundiflorus* and *Phlox diffusa*. Except for the abundant dwarf-shrub *Artemisia frigida*, scattered *Ericameria nauseosa* shrubs or occasional *Pinus ponderosa* trees, woody species are very sparse or absent. The exotic grasses *Poa pratensis* and *Bromus tectorum* are common in some of these stands. Diagnostic of this grassland association is the dominance of *Muhlenbergia montana* in the herbaceous layer and low cover of *Festuca arizonica*.

CONSERVATION RANK G3G4

DATABASE CODE Cegl001646

MAP CLASSES

Mountain Muhly Herbaceous Vegetation corresponds to the map classes Montane Grassland (map code 8), Montane Grassland (Rabbitbrush) (map code 9), and Montane Grassland (Bonito Park Historic Agricultural Field) (map code 10). The Rabbitbrush modifier refers to the Mountain Muhly Herbaceous Vegetation association with >5% total cover of *Ericameria nauseosa*. The Bonito Park Historic Agricultural Field was delineated from aerial photographs as a previous area of agricultural activity. This area is not predominantly mountain muhly dominated; however, it occurs within the Montane Grassland map class. Montane Grassland includes both Blue Grama Herbaceous Vegetation and Mountain Muhly Herbaceous Vegetation associations. These two grass associations were combined into one map class, due to often occurring as co-dominates and indistinguishable from aerial photography.

Montane Grassland is mapped as occurring mainly in small patches throughout the western half of the project boundary and only occurs in the project environs and was not mapped as occurring in Sunset Crater Volcano NM. The total area of Montane Grassland mapped in the park environs is 349 hectares within 156 polygons, this includes 148 hectares and 104 polygons in map code 8, 100 hectares and 51 polygons in map code 9, and 101 hectares and 1 polygon in map code 10.

COMMENTS

Global Dynamics

Muhlenbergia montana often grows in association with montane conifer forests, especially ones dominated by *Pinus ponderosa* and has developed a tolerance for relatively frequent fire regimes. Although *Muhlenbergia montana* resprouts after burning, it may take a few years to recover to pre-burn density (Fischer and Bradley 1987). These grasslands may be considered seral or an edaphic climax depending if there are environmental factors, such as aridity, that are preventing establishment of trees. Historically, much of the area where this association occurs was heavily grazed by livestock, primarily sheep and cattle (Shepherd 1975). Season of use is important in stands with both *Hesperostipa comata* and *Muhlenbergia montana*, fall grazing will favor *Hesperostipa comata* over the later blooming *Muhlenbergia montana* (Clary 1978). The reverse is true if grazing is always limited to summer. Overgrazing will reduce or eliminate *Hesperostipa comata*, *Muhlenbergia montana* and the other palatable species,

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

leaving the more grazing-tolerant *Bouteloua gracilis* and less palatable plants such as *Hymenoxys*, *Artemisia* and *Chrysothamnus* species to dominate the site Clary (1978).

ALLIANCE	<i>Pascopyrum smithii</i> Herbaceous Alliance

CLASSIFICATION CONFIDENCE LEVEL Weak

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Western Wheatgrass Herbaceous Vegetation is an uncommon association only found in the project environs. It occurs in sites that were recently burned and have high disturbance (i.e. roadsides, cinder quarries) to the west of Robinson Mountain and on Robinson Crater.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

The two relevés sampled within this association both occurred at an elevation of 2,160m. The slope was nearly flat (2-3%) and the substrate was cinder sand and gravel.

Globally

This grassland association is widespread in the northern and western Great Plains, Rocky Mountains, the intermountain western United States and possibly Canada. Elevation ranges from 600-3,000m. Stands occur on level to gently sloping terrain. They are found on alluvial fans, swales, river terraces, floodplains, valley bottoms and basins. The soils are deep (40-100 cm) and well-developed with clay, clay loam, and silt loam textures. Some stands occur on perched water tables

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Western Wheatgrass Herbaceous Vegetation had a total vegetation cover of 30- 45%. Absolute cover in the tree layer was 0-10%, 0-0.5% in the shrub layer, and 22-45% in the herbaceous layer. Species richness consisted of 16 species in both relevés.

Within the tree layer the cover is sparse with an occasional *Pinus ponderosa*. The shrub layer is also sparse with only an occasional shrub. The herbaceous layer was characterized by *Pascopyrum smithii* with 20-35% total cover.

Globally

This association is characterized by a moderate to dense (40-100% cover) mixed grass herbaceous canopy that grows 0.5-1 m tall and is strongly dominated by *Pascopyrum smithii*. Other graminoids that co-occur and may achieve local dominance are *Koeleria macrantha*, *Eleocharis palustris*, and *Poa* spp. Many other species common in midgrass prairies are also found in this community. These include *Artemisia frigida*, *Artemisia ludoviciana*, *Achillea* sp., *Carex* spp., *Cirsium* spp., *Eriogonum* spp., *Bouteloua gracilis*, *Nassella viridula*, and *Hesperostipa comata* (= *Stipa comata*). Shrubs and dwarf-shrubs are rare in this community, but occasional woody plants such as *Symphoricarpos* spp., *Ericameria nauseosa*, or *Krascheninnikovia lanata* may be present. Introduced species, such as *Bromus tectorum*, *Bromus inermis*, *Poa pratensis*, *Melilotus* spp., *Cirsium arvense*, *Taraxacum officinale*, or *Salsola kali*, are common in some stands, especially where disturbed.

CONSERVATION RANK G3G5Q

DATABASE CODE Cegl001577

MAP CLASSES

Western Wheatgrass Herbaceous Vegetation corresponds to the map class Ponderosa Pine Invasive Herbaceous Vegetation (map code 16). Western wheatgrass is not an invasive species; however, it is often associated with reseeding efforts and other areas of disturbance and therefore was lumped into this map class. Ponderosa Pine Invasive Herbaceous Vegetation includes both the Western Wheatgrass Herbaceous Vegetation and Ponderosa Pine Wooded Invasive Herbaceous Vegetation associations.

Ponderosa Pine Invasive Herbaceous Vegetation is mapped as occurring mainly in the northwestern half of the project environs around the base of cinder cones and on a cinder hill south of Bonito Park. It is not mapped as occurring in Sunset Crater Volcano NM. The total area of Ponderosa Pine Invasive Herbaceous Vegetation mapped in the park environs is 309 hectares within 19 polygons.

COMMENTS

Sunset Crater Volcano National Monument

Pascopyrum smithii is native to the United States; but it is not native to Arizona. However, *Pascopyrum smithii* is used in re-vegetation reseeding efforts by the Forest Service (FEIS 2001) and was possibly used to reseed the burned area northwest of Sunset Crater.

Global Comments

This community is similar to several others that are dominated or codominated by *Pascopyrum smithii*. As currently defined, it represents a western Great Plains and foothills version of the western wheatgrass types in the central Great Plains. Further work needs to be done to refine the differences in composition and environmental characteristics. See recent descriptions by Thilenius et al. (1995) (*Pascopyrum smithii* sodgrass steppe, a more playa-like wheatgrass type) and by Steinauer and Rolfsmeier (2000). In Nebraska, Steinauer and Rolfsmeier (2000) suggest that their stands may resemble *Pascopyrum smithii* - *Nassella viridula* Herbaceous Vegetation (CEGL001583).

Global Dynamics

In semi-arid climates, this association is found in relatively mesic topographic positions such as swales, river terraces, floodplains and basins that may be temporarily or intermittently flooded or in some classes, the fine textured soil sometimes perches the water table (Hansen et al. 1995, Hall and Hansen 1997). In more mesic climates it is found in extensive upland areas.

Pinus ponderosa Wooded Invasive Herbaceous Vegetation (Local Assemblage)

COMMON NAME Ponderosa Pine Invasive Herbaceous Vegetation

CLASSIFICATION CONFIDENCE LEVEL Not Rated, Unique to Monument

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Ponderosa Pine Invasive Herbaceous Vegetation occurs in areas of disturbance. Frequently the association is located where intensive logging activity has historically occurred. This association is mostly found in the project environs near Robinson Mountain.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

This association was sampled at an elevation range of 2,140-2,220m (average 2,200m). Slope varied from steep to none (0-20%) (average 9%). It was found on cinder sand and gravel.

MOST ABUNDANT SPECIES

Sunset Crater Volcano National Monument

<u>Stratum</u>	<u>Species</u>

Herbaceous	<i>Bromus tectorum</i>

ASSOCIATED SPECIES

Sunset Crater Volcano National Monument

Artemisia dracunculus, *Geranium caespitosum*, *Junipers osteosperma*, *Linaria dalmatica* ssp. *dalmatica*, *Ribes cereum*, *Thalictrum fendleri*

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

Ponderosa Pine Wooded Invasive Herbaceous Vegetation had a total cover of 28- 45% (average 38%). Absolute cover in the tree layer ranged from 5-25% (average 15%), in the shrub layer 2-5% (average 3%), and in the herbaceous layer 17-25% (average 15%). Species richness for all three relevés ranged from 19-23 species (average 21).

The tree layer was dominated by *Pinus ponderosa* with cover ranging from 5-25%. DBH for *Pinus ponderosa* ranged from 11-87cm (average 19cm). The shrub cover is sparse. The herbaceous layer consisted of a variety of weedy native and non-native species, most often dominated by *Bromus tectorum* (0.5-20% absolute cover) and *Artemisia dracunculus* that ranged from (0.5-15% absolute cover).

MAP CLASSES

Ponderosa Pine Invasive Herbaceous Vegetation is mapped as Ponderosa Pine Invasive Herbaceous Vegetation (map code 16). Ponderosa Pine Invasive Herbaceous Vegetation includes both the Western Wheatgrass Herbaceous Vegetation and Ponderosa Pine Wooded Invasive Herbaceous Vegetation associations. These two associations were combined into one map class due to both occurring in previously disturbed areas and in areas that were reseeded after recent burns.

Ponderosa Pine Invasive Herbaceous Vegetation is mapped as occurring mainly in the northwestern half of the project environs around the base of cinder cones and on a cinder hill south of Bonito Park. It is not mapped as occurring in Sunset Crater Volcano NM. The total area of Ponderosa Pine Invasive Herbaceous Vegetation mapped in the park environs is 309 hectares within 19 polygons.

COMMENTS

Sunset Crater Volcano National Monument

Ponderosa Pine Invasive Herbaceous Vegetation had a variety of understory weedy herbaceous species that varied in composition and abundance between measured relevés. The herbaceous layer may vary annually and further data collection will be needed to understand the ecology and long-term dynamics of this association within Sunset Crater environs.

This unique community must be further sampled on the Colorado Plateau to determine if it is unique to Sunset Crater Volcano NM or if it is found across the landscape. Currently it has no global information, conservation rank or database code. Observations and descriptions of additional occurrences are required to confirm it as an association within the NVCS.

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

Ericameria nauseosa – *Pericome caudata* Rock Outcrop Sparse Vegetation (Local Assemblage)

COMMON NAME Rubber Rabbitbrush - Mountain Tail-leaf Rock Outcrop Sparse Vegetation

CLASSIFICATION CONFIDENCE LEVEL Not Rated, Unique to Monument

USFS WETLAND SYSTEM Upland

RANGE

Sunset Crater Volcano National Monument

Proposed association Rubber Rabbitbrush - Mountain Tail-leaf Rock Outcrop Sparse Vegetation occurs as small isolated stands of vegetation on lava outcrops within cinder barrens. It is found within Sunset Crater Volcano on cinder cones and within cinder barrens in the northern section of the park. In the project environs this vegetation type occurs mainly on the cinder barrens in the northeastern section of the mapping zone and on cinder cones in the northwestern section of the mapping zone.

ENVIRONMENTAL DESCRIPTION

Sunset Crater Volcano National Monument

Only one relevé was sampled of Rubber Rabbitbrush - Mountain Tail-leaf Rock Outcrop Sparse Vegetation. It had an elevation of 2100m, a slope of 10%, and was on lava outcrops within cinder barrens.

MOST ABUNDANT SPECIES

Sunset Crater Volcano National Monument

Stratum

Shrub

Species

Ericameria nauseosa, *Pericome caudata*

VEGETATION DESCRIPTION

Sunset Crater Volcano National Monument

In the one sampled relevé of Rubber Rabbitbrush - Mountain Tail-leaf Rock Outcrop Sparse Vegetation total vegetation cover was 7%. The relevé was sparse and within the tree layer the cover was 1%, the shrub layer 6%, and the herbaceous layer 2%. The tree and herbaceous layer were sparse. The shrub layer consisted of *Ericameria nauseosa* (2%) and *Pericome caudata* (3%). Species richness was low with only six species.

MAP CLASSES

The proposed association Apache Plume - Tasselflower Brickellbush – (Ocean Spray Scree) Scree Shrubland is represented by map class Rock Outcrop and Scree Shrubland (Map Code 3). Rock Outcrop and Scree Shrubland combines both Apache Plume - Tasselflower Brickellbush – (Ocean Spray Scree) Scree Shrubland and Rubber Rabbitbrush - Mountain Tail-leaf Rock Outcrop Sparse Vegetation local vegetation assemblages. These two assemblages were combined into one map class due to occurring in very small patches in similar habits throughout the entire project area.

This was mapped as very small polygons throughout the entire project area. The total area of Rock Outcrop and Scree Shrubland mapped in Sunset Crater Volcano is less than 0.5 hectares within 2 polygons and in the park environs is 4 hectares within 11 polygons.

COMMENTS

Sunset Crater Volcano National Monument

This monument specific community must be further sampled on the Colorado Plateau to determine if it is unique to Sunset Crater Volcano NM or if it is found across the landscape. Currently it has no global information, conservation rank or database code. Observations and descriptions of additional occurrences are required to confirm it as an association within the NVCS.

APPENDIX G

G. Sunset Crater Volcano National Monument Species List

(Species list was compiled from the relevé data collected in 1999
as part of the USGS-NPS National Mapping Program)

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

Family	Scientific Name	Common Name
Anacardiaceae	<i>Rhus trilobata</i> Nutt.	skunkbush sumac
Asclepiadaceae	<i>Asclepias subverticillata</i> (Gray) Vail	horsetail milkweed
	<i>Asclepias</i> sp. L. ¹	milkweed
Asteraceae	<i>Ageratina herbacea</i> (Gray) King & H.E. Robins.	fragrant snakeroot
	<i>Ambrosia acanthicarpa</i> Hooke.	flatspine burr ragweed
	<i>Ambrosia psilostachya</i> DC.	Cuman ragweed
	<i>Artemisia campestris</i> ssp. <i>pacifica</i> (Nutt.) Hall & Clements	field sagewort
	<i>Artemisia carruthii</i> Wood ex Carruth.	Carruth's sagewort
	<i>Artemisia dracunculus</i> ssp. <i>dracunculus</i> L.	tarragon
	<i>Artemisia ludoviciana</i> Nutt.	white sagebrush
	<i>Artemisia</i> sp. L.	sagebrush
	<i>Bahia dissecta</i> (Gray) Britt.	ragleaf bahia
	<i>Brickellia californica</i> (Torr. & Gray) Gray	California brickellbush
	<i>Brickellia eupatorioides</i> var. <i>eupatorioides</i> (L.) Shinnery	false boneset
	<i>Brickellia grandiflora</i> (Hook.) Nutt.	Tasselflower brickellbush
	<i>Chaetopappa ericoides</i> (Torr.) Nesom	rose heath
	<i>Cirsium wheeleri</i> (Gray.) Petrak	Wheeler's thistle
	<i>Ericameria nauseosus</i> ssp. <i>nauseosa</i> var. <i>nauseosa</i> (Pallas ex Pursh) Nesom & Baird	rubber rabbitbrush
	<i>Erigeron divergens</i> Torr. & Gray	spreading fleabane
	<i>Erigeron flagellaris</i> Gray	trailing fleabane
	<i>Erigeron</i> sp. L.	fleabane
	<i>Gaillardia pinnatifida</i> Torr.	red dome blanketflower
	<i>Gutierrezia sarothrae</i> (Pursh) Britt. & Rusby	broom snakeweed
	<i>Helenium arizonicum</i> Blake	Arizona sneezeweed
	<i>Helianthus annuus</i> L.	common sunflower
	<i>Hymenopappus filifolius</i> var. <i>lugens</i> (Greene) Jepson	Idaho hymenopappus
	<i>Hymenoxys richardsonii</i> (Hook.) Cockerell	pingue rubberweed
	<i>Lactuca serriola</i> L.	prickly lettuce
	<i>Packera multilobata</i> (Torr. & Gray ex Gray) W.A. Weber & A. Löve	lobeleaf groundsel
	<i>Senecio</i> sp. L.	ragwort
	<i>Stephanomeria minor</i> (Hook.) Nutt. var. <i>minor</i>	narrowleaf wirelettuce
	<i>Stephanomeria</i> sp. Nutt.	wirelettuce
	<i>Tetradymia canescens</i> DC.	spineless horsebrush
	<i>Tragopogon dubius</i> Scop.	yellow salsify
Berberidaceae	<i>Mahonia fremontii</i> (Torr.) Fedde	Fremont's mahonia
Boraginaceae	<i>Cryptantha cinerea</i> var. <i>jamesii</i> Cronq.	James' cryptantha
	<i>Cryptantha</i> sp. Lehm. ex G. Don	cryptantha
	<i>Lappula occidentalis</i> (S. Wats.) Greene	flatspine stickseed
	<i>Lappula</i> sp. Moench	stickseed
	<i>Lithospermum multiflorum</i> Torr. ex Gray	manyflowered stoneseed
Brassicaceae	<i>Arabis fendleri</i> (S. Wats.) Greene	Fendler's rockcress
	<i>Arabis</i> sp. L.	rockcress
	<i>Descurainia incana</i> ssp. <i>incana</i> (Bernh. ex Fisch. & C.A. Mey.) Dorn	mountain tansymustard

¹ Genera that do not include specific epithets are unique unidentified species.

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

	<i>Descurainia obtusa</i> (Greene) O.E. Schulz	blunt tansymustard
	<i>Descurainia sophia</i> (L.) Webb ex Prantl	herb sophia
	<i>Erysimum capitatum</i> (Dougl. ex Hook.) Greene	sanddune wallflower
	<i>Physaria newberryi</i> Gray	Newberry's twinpod
	<i>Sisymbrium altissimum</i> L.	tall tumbledmustard
Cactaceae	<i>Echinocereus</i> sp. Engelm.	hedgehog cactus
	<i>Opuntia</i> sp. P. Mill.	pricklypear
Capparidaceae	<i>Cleome serrulata</i> Pursh	Rocky Mountain beeplant
Chenopodiaceae	<i>Chenopodium album</i> L.	lambsquarters
	<i>Chenopodium berlandieri</i> Moq.	pitseed goosefoot
	<i>Chenopodium graveolens</i> Willd.	fetid goosefoot
	<i>Chenopodium leptophyllum</i> (Moq.) Nutt. ex S. Wats.	narrowleaf goosefoot
Commelinaceae	<i>Commelina dianthifolia</i> Delile	birdbill dayflower
Cupressaceae	<i>Juniperus deppeana</i> Steud.	alligator juniper
	<i>Juniperus osteosperma</i> (Torr.) Little	Utah juniper
	<i>Juniperus</i> sp. L.	juniper
Euphorbiaceae	<i>Chamaesyce fendleri</i> (Torr. & Gray) Small	Fendler's sandmat
	<i>Euphorbia brachycera</i> Engelm.	horned spurge
	<i>Euphorbia</i> sp. L.	spurge
	<i>Tragia ramosa</i> Torr.	branched noseburn
Fabaceae	<i>Alhagi maurorum</i> Medik.	camelthorn
	<i>Astragalus</i> sp. L.	milkvetch
	<i>Lotus wrightii</i> (Gray) Greene	Wright's deervetch
	<i>Lupinus argenteus</i> Pursh	silvery lupine
	<i>Lupinus</i> sp. L.	lupine
	<i>Oxytropis lambertii</i> Pursh	purple locoweed
	<i>Phaseolus angustissimus</i> Gray	slimleaf bean
Fagaceae	<i>Quercus gambelii</i> Nutt.	Gambel oak
Geraniaceae	<i>Geranium caespitosum</i> var. <i>eremophilum</i> (Woot.& Standl.) W.C. Martin & C.R. Hutchins	purple cluster geranium
Grossulariaceae	<i>Ribes cereum</i> var. <i>pedicellare</i> Brewer & S. Wats.	whisky currant
Hydrophyllaceae	<i>Phacelia crenulata</i> Torr. ex S. Wats.	cleftleaf wildheliotrope
	<i>Phacelia egea</i> (Greene ex Brand) Greene ex J.T. Howell	Kaweah River phacelia
	<i>Phacelia serrata</i> J. Voss	saw phacelia
	<i>Phacelia</i> sp. Juss.	phacelia
Lamiaceae	<i>Marrubium vulgare</i> L.	horehound
	<i>Monardella odoratissima</i> Benth.	mountain monardella
Liliaceae	<i>Yucca angustissima</i> Engelm. ex Trel.	narrowleaf yucca
	<i>Yucca baccata</i> Torr.	banana yucca
Linaceae	<i>Linum lewisii</i> Pursh	prairie flax
	<i>Linum neomexicanum</i> Greene.	New Mexico yellow flax
	<i>Linum</i> sp. L.	flax
Loasaceae	<i>Mentzelia pumila</i> Nutt ex Torr. & Gray	dwarf mentzelia
	<i>Mentzelia</i> sp. L.	blazingstar
Malvaceae	<i>Sphaeralcea</i> sp. St.-Hil.	globemallow
Nyctaginaceae	<i>Mirabilis decipiens</i> (Standl.) Standl.	broadleaf four o'clock
	<i>Mirabilis linearis</i> (Pursh) Heimerl	narrowleaf four o'clock

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

	<i>Mirabilis multiflora</i> (Torr.) Gray	Colorado four o'clock
	<i>Mirabilis</i> sp. L.	four o'clock
Oleaceae	<i>Forestiera pubescens</i> var. <i>pubescens</i> Nutt.	stretchberry
Onagraceae	<i>Gaura coccinea</i> Nutt. ex Pursh	scarlet beeblossom
	<i>Oenothera cespitosa</i> Nutt.	tufted evening-primrose
	<i>Oenothera</i> sp. L.	evening-primrose
Pinaceae	<i>Pinus edulis</i> Engelm.	twoneedle pinyon
	<i>Pinus flexilis</i> James	limber pine
	<i>Pinus ponderosa</i> P. & C. Lawson	ponderosa pine
	<i>Pseudotsuga menziesii</i> (Mirbel) Franco	Douglas-fir
Plantaginaceae	<i>Plantago patagonica</i> Jacq.	woolly plantain
Poaceae	<i>Achnatherum hymenoides</i> (Roemer & J.A. Schultes) Barkworth	Indian ricegrass
	<i>Agropyron desertorum</i> (Fisch. Ex Link) J.A. Schultes	desert wheatgrass
	<i>Andropogon hallii</i> Hack.	sand bluestem
	<i>Aristida divaricata</i> Humb. & Bonpl. ex Willd.	poverty threeawn
	<i>Aristida</i> sp. L.	threeawn
	<i>Bouteloua curtipendula</i> (Michx.) Torr.	sideoats grama
	<i>Bouteloua gracilis</i> (Willd. ex Kunth) Lag. ex Griffiths	blue grama
	<i>Bromus ciliatus</i> L.	fringed brome
	<i>Bromus rubens</i> L.	red brome
	<i>Bromus tectorum</i> L.	cheatgrass
	<i>Bromus</i> sp. L.	brome
	<i>Elymus elymoides</i> ssp. <i>elymoides</i> (Raf.) Swezey	squirreltail
	<i>Festuca arizonica</i> Vasey	Arizona fescue
	<i>Festuca</i> sp. L.	fescue
	<i>Hordeum jubatum</i> L.	foxtail barley
	<i>Muhlenbergia minutissima</i> (Steud.) Swallen	annual muhly
	<i>Muhlenbergia montana</i> (Nutt.) A.S. Hitchc.	mountain muhly
	<i>Muhlenbergia rigens</i> (Benth.) A.S. Hitchc.	deergrass
	<i>Pascopyrum smithii</i> (Rydb.) A. Love	western wheatgrass
	<i>Poa fendleriana</i> (Steud.) Vasey	muttongrass
	<i>Schizachyrium scoparium</i> ssp. <i>scoparium</i> (Michx.) Nash	little bluestem
Polemoniaceae	<i>Ipomopsis aggregata</i> ssp. <i>aggregata</i> (Pursh) V. Grant	scarlet gilia
Polygonaceae	<i>Eriogonum corymbosum</i> var. <i>aureum</i> (M.E. Jones) Reveal	crispleaf buckwheat
	<i>Eriogonum racemosum</i> Nutt.	redroot buckwheat
	<i>Eriogonum wrightii</i> Torr. ex Benth.	bastardsage
	<i>Eriogonum</i> sp. Mitchx.	buckwheat
Polypodiaceae	<i>Pellaea atropurpurea</i> (L.) Link	purple cliffbrake
	<i>Pellaea truncata</i> Goodding	spiny cliffbrake
Ranunculaceae	<i>Thalictrum fendleri</i> Engelm. ex Gray	Fendler's meadow-rue
Rosaceae	<i>Cercocarpus montanus</i> Raf.	alderleaf mountain mahogany
	<i>Chamaebatiaria millefolium</i> (Torr.) Maxim	fernbush
	<i>Fallugia paradoxa</i> (D. Don) Endl. ex Torr.	Apache plume
	<i>Holodiscus dumosus</i> (Nutt. ex Hook.) Heller	rock spirea
	<i>Purshia stansburiana</i> (Torr) Henrickson	Stansbury cliffrose
Rubiaceae	<i>Galium stellatum</i> Kellogg	bedstraw
	<i>Galium wrightii</i> Gray	Wright's bedstraw

USGS-NPS Vegetation Mapping Program
Sunset Crater Volcano National Monument

Salicaceae	<i>Populus tremuloides</i> Michx.	quaking aspen
Scrophulariaceae	<i>Castilleja integra</i> Gray	wholeleaf Indian paintbrush
	<i>Castilleja</i> sp. Mutis ex L. f.	Indian paintbrush
	<i>Linaria dalmatica</i> ssp. <i>dalmatica</i> (L.) P. Mill.	Dalmatian toadflax
	<i>Penstemon barbatus</i> (Cav.) Roth	beardlip penstemon
	<i>Penstemon clutei</i> A. Nels.	Sunset Crater beardtongue
	<i>Penstemon jamesii</i> Benth.	James' beardtongue
	<i>Penstemon</i> sp. Schmidel	penstemon
	<i>Pericome caudata</i> Gray	mountain tail-leaf
Solanaceae	<i>Verbascum thapsus</i> L.	common mullein
	<i>Physalis hederifolia</i> var. <i>fendleri</i> (Gray) Cronq.	Fendler's groundcherry

APPENDIX H

H. Visual Guide and Descriptions of the Sunset Crater Volcano National Monument Map Classes

Introduction

This document is a guide to the photointerpretation of vegetation map classes for Sunset Crater Volcano National Monument. It provides a ground photo image for each map class as well as at least one example of each map class as it appears on the aerial photographs.

This guide does not attempt to show all variations of each map class; only the most common or significant representations are included. The descriptions should be sufficient to give the user a feel for the imagery and an understanding of the relationships between the vegetation and the map classes. This guide describes the vegetation map classes and two separate photointerpreted coverages of aspen (*Populus fremontii*) and off-highway vehicle use.

How this guide is organized

This guide describes and illustrates every vegetation map class used in the Sunset Crater vegetation mapping project and the two photointerpreted coverages with one map class per page. The images are aerial photographs with their Mylar overlays scanned so as to show the photointerpreter's work. The assigned map class codes and the aerial photograph flight line numbers are in yellow or black depending on the visibility of the color on the photograph. Ground photos of each type are included where available. The photos are accompanied by a brief description of the distribution of the map class within the project area and how it generally appeared on the aerial photos. Other information about the map class or the polygon may be included if it improved understanding or recognition of that particular map class.

Merrick & Company of Aurora Colorado flew the color infrared (CIR) aerial photographs for SUCR on October 8, 1996. The photos were taken at a flight altitude of 6,000 feet above sea level using Kodak Aerochrome Infrared 2443 film. The photo mission was designed to take photos with about 30% side lap (between each flight line) and 60% overlap (along each flight line). The scale of the 9 x 9-inch photos is 1:12,000 (approximately 1 inch = 1000 ft.). Two sets of contact prints and positive transparencies were produced and used for stereoscopic interpretation. A total of 46 frames taken over 6 flightlines covered the project area.

Color Infrared Film (CIR)

CIR film is best for highlighting subtle changes in deciduous and wetland vegetation. Evergreen vegetation can also be distinguished using CIR film, although not as clearly as deciduous trees and shrubs. CIR film presents a "false color" picture that combines infrared reflectance with green and red visible bands. These differences in reflectance create differences in tone and color that can be easily distinguished and delineated as different plant communities. Reflectance is influenced by structure of the canopy, the orientation of the plants and their leaves, and the thickness and pigment content of leaves.

Texture is also important to the photointerpreter. For shrubs, texture is influenced by density of plants on the landscape, crown size and shape, and leaf size. Dense, medium-sized shrubs such as rabbitbrush give a grainy texture to the photographs. Small shrubs such as snakeweed show little or no texture, since the plants are about the same size as a small bunchgrass. Grasslands

tend to have a smooth texture, except where interrupted by prairie dog holes or anthills, which appear as pinhole-sized white dots. These are imprecise terms, but nonetheless provide important visual cues to the imagery.

CIR photography generally is not consistent enough to allow a species or type to be described precisely. Film batch, printing process, sun angle, light intensity, shadow, and exposure can all affect the appearance of CIR photography. For accurate mapping at SUCR, ground verification by the photointerpreter was very important for to successful interpretation of types with confusing or similar signatures.

Cinder Sparse Mosaic (1)

Location. This map class is scattered in small and large patches throughout the eastern half of the mapping area. Smooth slopes and windblown dunes of sparsely vegetated black cinder characterize it.

Photosignature. This map class has a unique signature because it is largely unvegetated volcanic cinder. The color ranges from a very dark greenish-black to a pale blue green. The texture is generally smooth, but sometimes it has a wavy texture created by dune formations. Small inclusions of vegetation appear generally as white dots and specks.

Lava Beds (2)

Location. This map class consists of the unvegetated portions of two large lava flows located near the center of the mapping area. It interfingers with map code 6 (Lava Bed Sparse Vegetation).

Photosignature. This map class has a unique signature because it is largely unvegetated lava flow. The color ranges from a very dark greenish-black to a pale blue green. The texture is rough and irregular, reflecting the broken surface of the lava. Small inclusions of vegetation appear generally as white dots or specks or as light blue-green smudges. Some areas of the flow were subsequently covered by volcanic ash and cinder; these areas appear smoother and much darker, and are often vegetated (not visible on this photograph).

Rock Outcrop and Scree Shrubland (3)

Location. This map class consists of a complex of shrubland plant communities characterized by their preference for rocky substrates. It occurs in very small polygons scattered throughout the mapping area.

Photosignature.

Only the larger occurrences of this type were visible on the aerial photos; even so, most are less than the minimum mapping unit in size. They appear as breaks in the dominant vegetation, characterized by a grayish color and rough texture. Some, as in the example pictured here, are linear in shape and partly obscured by trees.

Wild Buckwheat – Sand Bluestem Sparse Vegetation (4)

Location. This map class occurs in small polygons scattered in areas of deep cinder deposition. The best occurrences are on the upper parts of the Sunset Crater cone and in the northeastern part of the mapping area. The vegetation consists of the two named species with little other vegetation present.

Photosignature. For the most part, occurrences were mapped from direct field observations. This type is very similar in appearance to map code 7, Sand Bluestem Herbaceous Vegetation, which often occurs in adjacent polygons. The cinder substrate gives the map class a greenish-black color, while the vegetation contributes a blue-green cast (the grass) with tiny white specks (the shrubs).

Apache Plume / Cinder Sparse Vegetation (5)

Location. This map class is common and widespread, except in the southwestern corner and the western edge of the mapping area. It is best developed on lava outcrops mixed with volcanic cinder. It consists of sparse to dense stands of apache plume, generally with few associated species.

Photosignature. The characteristic signature for this map class consists of irregular small grayish white to blue-white speckles set in a matrix of smooth black cinder or rough black lava. The pink dots of trees are very sparse or absent.

Lava Bed Sparse Vegetation (6)

Location. This map class is closely associated with map code 2 (Lava Beds). It includes small patches of several different kinds of vegetation, including aspen woodlands, ponderosa pine woodlands, apache plume shrublands, and mixed shrublands that include ocean spray. It is generally restricted to the lava flows near the center of the mapping area.

Photosignature. Because of the variety of plant communities included within this map class, the signature is also somewhat variable. The map classes are associated with the two large lava flows, so they are either within or along the margins of the flows. The map class appears as a light bluish-white patch, with a gritty texture if shrubs are present, or small red-brown dots where aspens or ponderosa pines grow. This example is from the large lava flow north of the main park road.

Sand Bluestem Herbaceous Vegetation (7)

Location. This map class is restricted to cinder slopes on the eastern and southern flanks of Sunset Crater. It consists of sparse but nearly pure stands of sand bluestem growing in volcanic cinder.

Photosignature. The characteristic signature for this map class consists of minute grayish white to blue-white specks set in a matrix of smooth greenish-black cinder. A thin litter layer sometimes imparts a whitish cast to the matrix. The texture of the specks is generally finer and more regular than that of map codes 4 or 5. This example is from the rim of Sunset Crater.

Montane Grassland (8-10)

Location. This map class is best developed in the western part of the mapping area. It includes native grasslands of blue grama and mountain muhly as well as more disturbed situations that include stands of rabbitbrush or native forb species (such as Bonito Park).

Photosignature. Native bunchgrass grasslands (8) appear as light gray, smooth patches, usually within areas of ponderosa pine or other woody vegetation. Stands of rabbitbrush (9) are distinguishable by the texture of the small bumps the shrubs create. Bonito Park (10) forms a single class, marked by the presence of fence lines and lines marking the edge of old fields, visible in the center of the right picture.

Pinyon Pine – Utah Juniper / Blue Grama Woodland (11-12)

Location. This map class occurs in large patches on the slopes of the cinder cones within the mapping area. There are also stands on the windswept upper slopes of some of the larger cinder cones in the area. The understory is usually poorly developed, but may include sparse grasses or shrubs. Areas with more open pinyon-juniper canopy generally have a better-developed understory.

Photosignature. Mature pinyon pines and Utah junipers (11) are easily distinguished from ponderosa pine by their flatter, more irregular crowns and generally shorter stature (little or no shadow). Sparse stands (12) generally have a significant cover of shrubs, including skunkbush sumac (*Rhus trilobata*) and apache plume (*Fallugia paradoxa*), which contribute a rough texture to the appearance of the understory.

Limber Pine Woodland (13)

Location. This map class is restricted to small polygons on the exposed, south-facing upper slopes of O’Leary Peak.

Photosignature. This map class was mapped from field observations. In general the appearance is similar to that of sparse pinyon-juniper stands (12), except that the individual tree crowns tend to be taller and broader. The understory is generally sparse, but appears white because the ground is covered with litter. The pictured example is from the shoulder of O’Leary Peak below the summit ridge.

Ponderosa Pine / Cinder Woodland (14)

Location. This map class is widespread, occurring in large areas in a north-south belt separating map codes 15 (Ponderosa Pine/Montane Grass Mosaic) and 17 (Ponderosa Pine/Apache Plume). While scattered clumps of grass or shrubs may occur in the understory, the general ground cover is barren cinder. This type contains most of the known populations of the rare beardtongue (*Penstemon cluteii*).

Photosignature. Ponderosa pines appear as reddish-brown spots, generally accompanied by significant black shadows. White patches, occurring around the base of individual trees, are the result of pine litter, not a grass understory. The ground between the tree crowns has the greenish-black appearance of barren cinder.

Ponderosa Pine / Montane Grass Mosaic (15)

Location. This map class is widespread, occurring in large polygons in the western third of the mapping area. Blue grama and/or mountain muhly may form a significant understory layer.

Photosignature. As in map code 14, ponderosa pine appears as reddish-brown spots accompanied by significant black shadows. The ground between the tree crowns usually appears uniformly light gray because of a combination of grass understory and pine litter. This example is immediately north of Bonito Park. The type may contain small inclusions of map code 17 (Ponderosa Pine/Apache Plume) and map code 14 (Ponderosa Pine/Cinder).

Ponderosa Pine Invasive Herbaceous Vegetation (16)

Location. This map class occurs in large polygons in the west central part of the mapping area, in parts of the area that burned 5-30 years ago, along disturbed roadsides and in the vicinity of the larger gravel pits. In these areas, invasive, non-native species became dominant in the understory, forming dense herbaceous stands where trees were killed, and forming the understory in areas where the canopy trees survived.

Photosignature. This map class is a mixture of wooded and herbaceous vegetation. As in map code 14, ponderosa pines appear as reddish-brown spots, generally accompanied by long black shadows. Some areas lack tree cover; many of the burned trees have fallen and appear as narrow gray lines on the light yellowish-gray of the invasive herbaceous vegetation.

Ponderosa Pine / Apache Plume Woodland (17-19)

Location. This common and widespread map class occurs in large polygons throughout the mapping area, although most of the type is in the eastern half of the area. Apache plume shrubs and sometimes rabbitbrush shrubs form a significant understory in open ponderosa pine woodlands.

Photosignature. In the best developed examples (17), ponderosa pine appear as red-brown spots, usually associated with larger, oblong black shadows. The understory appears rough-textured because of the shrubs. Rabbitbrush shrubs are small, white, somewhat fuzzy round specks, whereas Apache plume appears as irregularly-shaped white or red-brown specks. The dark cinder/lava substrate is more evident in examples with a sparse ponderosa overstory (19). Mixed ponderosa-pinyon-juniper examples (18) tend also to have a sparse overstory of trees.

Ponderosa Pine / Sand Bluestem Woodland (20)

Location. This map class is best developed outside the park boundary. However, a few small polygons occur within the mapping area, on the flanks of Sunset Crater and smaller cinder cones in the vicinity. This class was mapped primarily from observations made in the field.

Photosignature. There is little in the aerial photosignature to distinguish this type from map code 14 (Ponderosa Pine/Cinder Woodland) or map code 15 (Ponderosa Pine/Montane Grass Mosaic). Because the canopy is usually open, the grass understory sometimes appears as regularly spaced tiny white specks against the greenish-black cinder substrate.

Douglas-fir Forest (21)

Location. This map class includes all stands where Douglas-fir is dominant or co-dominant with ponderosa pine or limber pine. Within the mapping area, this type is restricted to steep, north-facing upper mountain slopes on lava and mixed lava-cinder substrates.

Photosignature. The principal distinguishing characteristic of this map class is the dense, dark canopy of red-brown trees with consistently pointed crowns. Very little of the black cinder/lava substrate is visible. When viewed in stereo, the steepness and northerly aspect of the habitat is evident. This example is from the summit ridge of O'Leary Peak.

OTHER MAPPING COVERAGES

OFF-Highway Vehicle (OHV) Class

Location. The OHV Class was used to delineate disturbed areas surrounding SUCR. The highest concentration of OHV use appeared in the south, east and northeast portions of the project area.

No Ground Photo

Photosignature. This class is characterized by having linear lines resulting from temporary tracks left by OHVs. Tracks usually cross and radiate from a common starting point, usually an established road, pull-out or parking lot. Tracks on cinders appear slightly lighter than undisturbed sites. Tracks through vegetation usually expose the cinder substrate.

Quaking Aspen / Cinder Woodland

Location. The Quaking Aspen / Cinder Woodland Class was used to delineate small stands of aspen (*Populus tremuloides*) in and around SUCR. Only two patches were mapped using four polygons. One patch occurred within the monument just south of the Sunset Crater road on the north slope of Lenox Crater. The other patch occurred in the northwest portion of the study area in the project environs. Other scattered aspen stands were not big enough to map.

Photosignature. Aspen trees were difficult to distinguish from ponderosa pines due in part to their intermixing and the pale color of the infrared photography. Aspen trees canopies were slightly pinker than pines and appeared as “fluffs” rather than cones. Ground verification by the ecologists supplemented the photo interpretation for this class.

Maine Agricultural Experiment Station

Acknowledgments

The writer wishes to express his appreciation to the following:

Dr. Harold E. Young, Professor Howard Mendall and Professor Malcolm Coulter for their guidance, assistance and support throughout all phases of this research project.

The Eastman Kodak Company for making the film available and the U. S. Geological Survey Photographic Laboratory for making the Ektacolor prints.

The James W. Sewall Company of Old Town, Maine for flying and for processing much of the photography.

The Maine Department of Inland Fisheries and Game, the Delta Waterfowl Research Station and S. T. Dillon for loaning photography.

The Wildlife Management Institute for providing funds specifically for this project.

The students, faculty members and biologists who participated as photo interpreters and assisted in preparation of the manuscript.

My wife, Janice, for typing preliminary drafts and to Maxine Hotne for typing the final copy.

Foreword

David Olson, who conducted this study for his Master's thesis in wildlife management, had previously served in the United States Air Force for two years as a photo interpretation officer. His interest and skills in photo interpretation were essential to the pursuit of this research project.

This is one of the very first studies to explore the use of air photos for the identification of marsh vegetation in a clear cut scientific manner. It can serve as a guide for future studies of other low growing species that are important in wildlife management.

Albert D. Nutting

School of Forestry

Summary and Conclusions

Aerial photographs of marsh habitat in Merrymeeting Bay, Maine, were studied to determine the kind of information relative to marsh vegetation that could be obtained from them, and also to determine the accuracy of the photographic interpretation. Four films were exposed at three altitudes over the same section of the marsh. On the basis of the photographic images, the vegetation on the study area was classified into 11 types: wildrice, river bulrush, round stem bulrush, yellow waterlily, pickerel weed, sweetflag, three-square bulrush, submersed aquatics, mixtures of the above, sand, silt, and high tide zone. Eighty areas representing all of these types were selected for interpretation tests. Each area was identified on the ground and accurately located on the aerial photography. Seven individuals, representing four levels of photo interpretation experience and/or experience in marshes, interpreted the 80 areas on the aerial photographs. The photo interpretations were compared with the ground identifications. The most important of the results were analysed statistically. The following conclusions may be deduced from this study:

1. The testing procedure appeared to be satisfactory for evaluating film, scales, and interpreters. It also seemed adequate for the classification of vegetation with the exception of three-square bulrush.
2. The classes of vegetation, recognizable on the aerial photographs, are similar to the plant associations that can be recognized on the ground with the exception of plants which usually grow in sparse stands.
3. There were no differences between the relative accuracies of interpretations on the four film materials.
4. With each increase in the scale of photography*, an increase in accuracy of interpretation was obtained. The increase (10 per cent) between scales of 1:20,000 and 1:12,000 was larger than the increase (5 per cent) observed between the scales of 1:12,000 and 1:5,000.
5. Biologists who have had experience in ecology of marshes, even though lacking prior training in photo interpretation, were able to interpret aerial photographs of marshes more accurately than experienced photo interpreters who had no experience in marshes.

* The representative fraction is the simplest method of expressing scales of aerial photography, and it is used in this report. At 1:5,000, one unit of measurement on the photograph equals 5,000 of the same units on the ground.

6. Training in the satisfactory use of the stereoscope can be accomplished in two hours or less. Likewise, only three to ten hours of practice in the identification of images on aerial photography (provided training aids and/or instruction are available) will permit interpretation of such aerial photographs with a relatively high degree of accuracy.
7. The images produced on aerial photographs result as much from the physical structure of the plant or stand of vegetation as they do from the color or tone of the plant.
8. Density of the marsh vegetation could not be interpreted accurately from the photographs, regardless of scale.
9. Mixtures of vegetation were interpreted with less accuracy than were pure stands.
10. Photographic penetration of water was less than two feet with the film materials used.
11. Aerial photographs are a useful means of studying marshes. In addition to recognizing the general types of marsh vegetation and the broad ecological zones, many plant species and associations can be recognized with a reasonable degree of accuracy.

THE USE OF AERIAL PHOTOGRAPHS IN STUDIES OF MARSH VEGETATION¹

DAVID P. OLSON²

Introduction

The physical and biological characteristics of a marsh are constantly changing. Some of these changes are slow and may progress for centuries, while others may be comparatively rapid. One of the biological characteristics which may change either slowly or rapidly is plant composition.

The evaluation of marshes for wildlife purposes and the selection of management procedures is dependent upon a knowledge of the variety, quantity, and location of marsh plants. Several methods have been devised to measure the composition of such vegetation. Information from quantitative sampling procedures is accurate, but it is costly as well as time-consuming to obtain. By general observation, less accurate information can be economically obtained, but it is often inadequate for use in management.

Aerial photographs have been used with a high degree of success to obtain quantitative information of certain natural resources, but their use in marsh ecology has been only partially determined. The purpose of this investigation was to further evaluate aerial photography as a means of studying marsh vegetation.

The objectives were:

1. To determine the type of information about marsh plants that may be obtained by studying aerial photographs.
2. To compare four film materials for use in aerial photography of a marsh.
3. To compare three scales of aerial photography of a marsh.
4. To compare interpretations by individuals of varying experience in marsh ecology and/or aerial photography.

Twelve aerial photographic coverages were obtained of a portion of Merrymeeting Bay, Maine, on August 25, 1957. Test areas on these photographs have been interpreted by seven photo interpreters, and the interpretations were checked against the actual stands of vegetation or portions of marsh habitat.

¹ Contribution from the Maine Cooperative Wildlife Research Unit, Orono, Maine: Maine Department of Inland Fisheries and Game, University of Maine, Wildlife Management Institute, and the Bureau of Sport Fisheries and Wildlife, U. S. Department of the Interior, cooperating.

² Currently a member of the faculty at the University of New Hampshire Forestry Department.

Material and Methods

The study area

Merrymeeting Bay is a large, shallow body of water at the junction of the Kennebec and Androscoggin rivers near Bowdoinham, Sagadahoc County, Maine. Its waters are fresh, and it has an average tide of four feet. According to the classification of Shaw and Fredine (1956), it is a combination of shallow fresh coastal and deep fresh coastal marsh.

At low tide a variety of vegetation may be seen. Dense stands of wildrice³ (*Zizania aquatica*) and yellow waterlily (*Nuphar spp.*) grow in the numerous coves and along five sluggish tidal rivers. Farther out in the bay are large expanses of silt and sand. Clumps of sweetflag (*Acorus Calamus*), pickerel weed (*Pontederia cordata*), soft stem bulrush (*Scirpus validus*), and yellow waterlily are scattered over the silt areas. Various species of submersed aquatics and three-square bulrush (*Scirpus americanus*) also grow on the open areas of silt, but their growth is diffuse. Typical of the sandy areas are large, dense stands of bulrush (*Scirpus validus* and *Scirpus fluvialis*). These bulrush stands are called "islands" by residents of the bay.

At high tide, only the tops of the bulrush and wildrice remain above the water, giving the bay the appearance of an expansive lake with scattered, short, emergent vegetation.

An area approximately three miles long and one-half mile wide which contained a variety of marsh vegetation was selected to be photographed (figure 1).

The reasons for choosing Merrymeeting Bay as an area in which to study marsh vegetation were:

1. It contained an excellent abundance and variety of marsh plants.
2. The vegetation could be examined in detail during low tides.
3. Aerial photographs of the area, which were taken in 1956, were available for preliminary study.
4. Merrymeeting Bay is an important waterfowl hunting area.

Photographic films and scales

The four types of film available for this study were two panchromatic films, Kodak Super-XX Aerographic and Kodak Plus-X Aerecon; and two color films, Kodak Ektachrome Aero, High Contrast (a positive color transparency film), and Kodak Ektacolor SO-1185, a color negative film. Black and white prints were made from the panchromatic films, and color prints from the color negative film. The color

³ Common names of plants are primarily from Hotchkiss (1950). Scientific nomenclature is taken from Fernald (1950).

MERRYMEETING BAY

Figure 1

Merrymeeting Bay and the Area Photographed

transparencies were placed in cellophane envelopes and studied on a light table.

The films were exposed with filters recommended by the manufacturer. A minus blue (haze and contrast) filter was used with both panchromatic films. The color negative film was exposed through a Wratten 2A (minus ultra violet and blue) filter. Various filters were used in exposing the color transparencies. These were selected by the photographer according to the film manufacturer's instructions, and the haze conditions at the time of photography.

As the scale of aerial photographs increases, the amount of detail in the photographic images increases, and it is possible to distinguish smaller differences in the heights of objects (figure 4). To evaluate the effects of these differences on the interpretation of marsh vegetation, all four films were exposed through an 8.25 inch focal length lens at altitudes of 3,360 feet, 8,250 feet, and 13,750 feet. The resulting scales of photography were 1:5,000, 1:12,000, and 1:20,000.

Photographic conditions

It was decided that photographs would be most useful if taken when the marsh vegetation was at its maximum development. This decision was based primarily on the results obtained from the photographs of Merrymeeting Bay made in 1956, and partially on estimation. Other conditions that were necessary for exposing the films were low tides and clear weather. Morning low tides were preferable since haze and clouds usually developed by early afternoon.

The photographs were taken at low tide on the morning of August 25, 1957. The time of photography extended from one-half hour before low tide until one hour and 45 minutes after. By the time the last 1:20,000 exposures were made, the tide had risen considerably (appendix I). Field observations at the time of photography indicated that the vegetation was slightly beyond maximum growth, as the wild-rice had produced fruit, and the pickerel weed leaves were starting to deteriorate.

Photo interpreters

Studies (although not pertaining to marsh vegetation) have indicated that persons who are most experienced with subjects photographed are the best interpreters of the photographs (DeLancie, 1957). Because of a general lack of familiarity with aerial photographs, many persons feel that special training and experience are necessary to interpret them.

Seven individuals of varying levels of experience in marsh ecology

and/or photo interpretation, were selected to ascertain variations in interpretive ability. All seven were given the Moessner Floating Circles Test (Moessner, 1954) to determine if they had normal stereoscopic perception. The experience, occupation, and stereoscopic perception scores of the interpreters are given in table 1. Interpreter A was the most experienced in using aerial photographs of marshes. His experience was obtained in the Delta Marsh, Manitoba, and at Merrymeeting Bay, Maine. Interpreters B and C were wildlife biologists, both of whom have had considerable experience in marshes. They were familiar with the Merrymeeting Bay marsh, but they had not used aerial photographs in the field except to a very limited extent. Interpreters D and E had both used aerial photographs extensively, but little or none of their experience was with marsh vegetation. Interpreters E and F were students in wildlife conservation with little or no experience in marshes or with aerial photographs.

Table 1
Experience, Occupation, and Stereo Perception Scores* of the
Photo Interpreters

Interpreter	Interpretation experience	Marsh experience	Occupation	Stereo perception
A	extensive	extensive	wildlife graduate student	100
B	little	extensive	biologist	96
C	very little	extensive	biologist	96
D	extensive	little	professor of photogrammetry and forestry	96
E	extensive	little	specialist in soil interpretation	96
F	very little	little	wildlife student	88
G	very little	little	wildlife graduate student	96

*Any score of 80 or more is considered good stereo perception.

Young (1956) indicated that the accuracy of photo interpretation varied with a person's interest in the subject and photography. No comparisons of interest between interpreters were made, but it is probably correct to assume that the interest of each was high. All of the test personnel voluntarily spent considerable time interpreting the aerial photography.

Establishment of a classification scheme

Before interpretation of aerial photography can be made, the images on the photographs and their counterparts on the ground must be classified into recognizable groups. The procedure recommended

by Young and Stoeckeler (1956) was employed in this study. The steps in this procedure are field reconnaissance, trial interpretations, and field verifications.

Prior to the time the test photographs were taken, field reconnaissance¹ was conducted by utilizing the 1956 aerial photographs. The images on the 1956 photographs were compared with areas in the marsh and a tentative classification was established. Trial interpretations employing the tentative classifications were made and verified in the field, and the classification scheme was modified to permit increased speed and accuracy of interpretation.

The final classification scheme for this study contained 11 types: wildrice, round stem bulrush, river bulrush, yellow waterlily, pickerel weed, sweetflag, submersed aquatics, three-square bulrush, sand, silt, and high tide zone.² It was also decided to designate density of vegetation as sparse, medium, or dense. Complete descriptions of each of the 11 types are provided in appendix II.

Initial phase of interpretations

For the initial tests 210 areas of varying tone and color were selected on the 1:5,000 color transparencies. These were then interpreted by interpreter A. Since the color prints were not available at the time, the 210 test areas were interpreted on each of the nine remaining film/scale combinations. The interpreted identity and density were recorded for each area. It is possible that clues to the identity of test areas may be obtained when interpreting one set of aerial photographs and employed while interpreting the next set. To reduce this "carry-over" of information, not more than one photographic coverage was interpreted in any one day; also, for this reason, the coverages which were believed to be most difficult were interpreted first, and the least difficult last. An Abrams, Model CB1, 2-4 lens stereoscope was used for all interpretations in the study.

When the initial phase of photo interpretation was completed, each of the 210 test areas was verified in the field according to the classification scheme. Density and vegetation composition were recorded for each area (table 2). The initial interpretations were compared with field identification with the following results:

1. An average accuracy of 78 per cent was obtained.
2. Little difference in accuracy was noted among the four kinds of photography.

¹ During the initial studies the author refrained from going into the area which was to be photographed in order to avoid bias in his interpretation. The type called high tide zone in this study is "coastal shallow fresh marsh", as classified by Shaw and Fredine (1956).

Table 2
Composition of Interpretation Tests in Terms of Vegetative Types and Densities

Type	Initial interpretations (210 areas)				Initial interpretations (80 areas)			
	Number of areas	Densities sparse	attempted medium	dense	Number of areas	Densities sparse	attempted medium	dense
wildrice	21	1	—	4	8	1	—	1
yellow waterlily	32	9	15	9	8	2	2	—
pickerel weed	15	1	8	5	6	1	2	1
river bulrush	7	—	—	—	7	—	—	—
round stem bulrush	37	5	13	18	8	2	2	2
sweetflag	24	—	3	13	8	—	2	2
submersed aquatic	9	1	2	2	7	1	2	2
three-square bulrush	7	3	4	—	5	2	2	—
high tide zone	9	—	—	—	5	—	—	—
sand	5	—	—	—	5	—	—	—
silt	8	—	—	—	6	—	—	—
mixtures	28	—	—	—	7	—	—	—
Totals	202*	20	45	51	80	9	12	8

*This figure varies from the original 210 areas selected because 8 areas either were not located on the ground or were eliminated because they were not included in the 11 types listed.

3. More accuracy was obtained on the photographs taken at a scale of 1:12,000 than on the 1:20,000 photographs.
4. Little difference in accuracy was obtained between the 1:12,000 and 1:5,000 scales.
5. Accuracy of interpretation varied with each of the 11 types in the classification.

Photo interpretation tests

To supplement the results of the initial interpretations, as well as to compare interpretations of individuals of varying experience in marsh ecology and/or photo interpretation, a series of photo interpretation tests was conducted. The test consisted of 80 acres selected from the original 210 by stratified random sampling. Each of the 11 classifications was represented between five and eight times, and seven areas of mixed vegetation were also included. Twenty-nine of the 80 areas were designated for interpretation of density.

Each of the interpreters who were to take these tests lacked experience with marsh vegetation and/or aerial photographs. Therefore, a period of orientation and training was necessary, but this training had to be conducted in such a way that no bias would be introduced. To minimize bias in training, each interpreter used the same reference material and the same practice interpretation areas. Also, the interpreter, rather than the instructor, decided when his training would cease.

The wildlife students utilized the most training (approximately ten hours). The experienced photo interpreters trained for the shortest time (two hours), and the biologists' training was intermediate in length. Variations in the amount of time spent in training resulted from personal desires for more or less training and differences in the amount of time which the interpreters could devote to training. An important part of the training program for each interpreter was stereo examination of areas pointed out by the instructor. Practice interpretations were made of areas which were selected during the field checks. The reference materials⁶ which were used in training were obtained during the field verification and included the following:

1. A description of each of the 11 types to be interpreted.
2. Photographs of each type taken from the ground and stereo pairs⁷ taken from a step ladder.
3. Ecological information for all types including location, soil, and associated types.

⁶ Reference materials are given in appendix II.

⁷ Stereo pairs are 2 photographs of the same area which are taken from different positions. When they are viewed with a stereoscope, a 3-dimensional image is obtained.

4. Descriptions of the photographic images (color and panchromatic) for the various types.
5. Examples⁸ of each type on the aerial photography.

Due to time limitations, each of the six interpreters did not interpret all sets of aerial photographs. However, the tests were arranged so that an interpreter of each experience level interpreted each film scale combination (table 8). As in the initial interpretations, precautions were taken to minimize "carry-over" of information. Also, the interpreters were instructed that the 80 test areas contained some of each of the 11 types and some mixtures, but they did not know the number. Instructions to interpret density on 29 of the test areas served as a clue that these areas were vegetative and not sand or silt, but the information gained in this matter was negligible. Scores of the tests were not revealed to the interpreters until all the tests were completed.

At first, the interpreters located the test areas, interpreted them, and recorded their decisions. After about one-third of the interpretation tests were completed, the instructor began pointing out test areas and recording the interpretations. This procedure shortened the time necessary to complete each test, reduced eye strain, and did not affect the interpretation, as judged by subsequent results in comparison with earlier scores.

Photographic penetration of water

During the initial phase of this investigation, several attempts were made to interpret depths of water from the 1956 photographs. In each case the interpretation was very inaccurate. Therefore, it was decided to measure water penetration on the test photography.

Seven markers, approximately ten feet square, were made by sewing strips of burlap and white cloth together. At low tide, immediately before the photographic flight, areas with approximately 1, 2, 3, and 4 feet of water depth were located and marked. One marker was placed on the bottom at each depth, and one marker was floated on the surface beside each bottom marker. During photography, depth readings were taken from a boat at the 4-foot marker. The water depth at each marker was measured immediately before and after photography, and calibrated for the time of photography. By this procedure water depths at four stations on each set of photographs were known within one or two inches. Secchi disk readings, which provide an index to the transparency of the water, were taken from the boat when the depth measurements were made.

Each of the 12 sets of photographs was examined by two in-

⁸ See aerial photographs of Merrymeeting Bay in Appendix I.

interpreters who recorded whether or not they could see the bottom markers at the stations.

Analytical procedures

Each interpretation was scored "one" when the area was identified correctly. If the interpreter called a single plant type a mixture, and the mixture included the correct type, it was scored "one-half" "One-half" score was also obtained for naming only part of a mixture. The total possible score was 80.

Interpreter C 1:20,000 Aerecon		Total score, 48 of 80 60% Density, 2 of 29 7% Mixture, 2 of 7 = 29%

Per cent Correct	100	100	57	0	75	67	100	26	67	100	84

Figure 2
Example of Table Used for Compiling Scores

Densities were scored separately. Since a density designation is meaningless when the vegetative type is not correctly stated, no credit was given for density designations unless the vegetation was identified correctly. Each correct density interpretation was scored "one", and the total possible score was 29.

The most convenient method for compiling these data is a table comparing interpretations with known identities, as used by Young and Stoeckeler (1956). Figure 2 is an example of such a table. It will be noted that the correct interpretations occur in a diagonal row from upper left to lower right. This table also depicts the number and identity of incorrect interpretations. One table was made from each of the 65 test interpretations, and from them, composite tables were compiled for each variable being investigated. The scores on mixture and density interpretations were compiled separately. The data were analyzed statistically, and these calculations are presented in appendix IV.

Results

Identification of marsh vegetation

There was considerable variation in the accuracy of identifying the 11 types of vegetation. In table 3 the total number of times each type was interpreted and the average accuracy of identification are listed. Wildrice, yellow waterlily, river bulrush, high tide zone, and sand were all interpreted with a high degree of accuracy, while pickerel weed, round stem bulrush, submersed aquatics, sweetflag, and silt were identified with an intermediate degree of accuracy. Of the 11 types studied, three-square bulrush alone was identified with an average accuracy of less than 50 per cent. The relative accuracies for the identification of types were the same in all tests regardless of interpreter, film, or scale.

Accuracy of identification in relation to scale

With an increase in the scale of photography, the accuracy of identifying most marsh types increased. However, there were some exceptions. At all scales, accuracy of identifying three-square bulrush stands varied little from what could be obtained by chance. By contrast, accuracy was consistently high for identification of the high tide zone. Table 4 contains the average accuracy for identification of vegetative types on the three scales investigated. The average increase in accuracy was 10 per cent between the 1:12,000 and 1:20,000 scales, and 5 per cent between the 1:12,000 and 1:5,000 scales. These differences are significant at the 99 per cent level (appendix IV).

Table 3
Variation in Accuracy of Identifying Eleven Classifications
of Marsh Vegetation
(all interpretations)

Marsh type	Number of interpretations	Average per cent accuracy
high tide zone	325	94
wildrice	525	93
sand	325	90
river bulrush	455	86
yellow waterlily	525	82
pickerel weed	390	75
silt	390	66
submersed aquatics	455	65
round stem bulrush	525	57
sweetflag	525	56
three-square bulrush	325	12

Accuracy of identification in relation to type of film

Since the accuracy in identifying the 11 types varied little on the four films tested (table 5), the differences between films were not statistically significant. Pickerel weed was correctly identified more often on the color films than on the panchromatic films. Sweetflag was identified less accurately on the color transparencies than with all other films, but the low accuracy with this plant occurred mainly on the 1:20,000 color transparencies.

Accuracy of identification in relation to experience of the interpreters

As might be expected, interpreters varied in their ability to identify the 11 types of vegetation. Comparison of the average scores as shown

Table 4
Accuracy of Identifying Eleven Classifications of Marsh
Vegetation on Three Scales of Photography

Type	Per cent accuracy		
	1:20,000	1:12,000	1:5,000
high tide zone	94	93	95
wildrice	88	92	98
sand	85	91	93
river bulrush	68	92	99
yellow waterlily	68	84	94
pickerel weed	63	80	82
silt	56	64	78
submersed aquatics	59	66	71
round stem bulrush	47	60	62
sweetflag	48	59	61
three-square bulrush	9	15	12
Average for all types	62	72	77

in table 6 indicated that the interpreters with the most experience with marshes identified the marsh types most accurately. A statistical analysis of the average scores of each interpreter, with the exception of interpreter A, indicated that there was a significant difference between the lowest and highest scores. There were no significant differences between the scores of biologists and students, and, with one exception, none between students and experienced interpreters.

Table 5
Accuracy of Identifying Eleven Classifications of Marsh Vegetation
on Four Film Materials

Type	Per cent accuracy for all scales			
	Aereographic	Aerecon	Ektachrome	Ektacolor
high tide zone	90	93	97	96
wildrice	94	93	92	92
sand	90	87	91	90
river bulrush	87	91	88	84
yellow waterlily	82	81	82	84
pickerel weed	65	73	82	82
silt	64	60	67	73
submersed aquatics	68	62	67	65
round stem bulrush	55	58	58	55
sweetflag	61	62	47	58
three-square bulrush	13	11	14	13
Combined average	70	70	71	72

The members of each pair of interpreters (B and C, D and E, and F and G) had similar scores for all scales and film materials. Also, their errors in identification were, for the most part, very similar. Statistical analysis of the scores obtained with the 1:12,000 photographs, on which all interpreters were tested, indicated that the interpreters in each pair did not vary significantly from one another (appendix IV).

Identification of mixed stands

Seven stands of mixed vegetation were included in the 80 test areas. Of these, only two were identified with appreciable accuracy. The seven mixtures and the number of times each was identified wholly correctly or one-half correctly are listed in table 7. Wildrice-round stem bulrush, and wildrice-river bulrush mixtures were recognized much more frequently than the remaining five.

In table 8 the mixture interpretation scores for all seven individuals are listed. Two interpreters obtained higher scores on mixtures than did the other five. As in identification of pure stands, no differences between film materials were noted, but the mixture score was higher with each increase in scale.

Table 6
Comparison of Interpretations—Accuracy in Per Cent of Identifying Marsh Vegetation

Interpretation of vegetation density

The relative accuracies of the interpretations of density for all interpreters and for each of the 12 sets of aerial photographs are listed in table 9. The average accuracy (23 per cent) varies little from what might be obtained by chance. Since there were three classes of density, chance should have yielded 33 per cent accuracy. However, to consider density, the vegetation first had to be identified correctly. Types of vegetation were identified with an average accuracy of 71 per cent. Multiplying the average accuracy of vegetation identification by expected accuracy due to chance (0.71×0.33) amounts to 22 per cent. This approximates the accuracy that was obtained.

Photographic penetration of water

The maximum depth at which any bottom marker could be identified on the photographs was 23 inches (table 10). At depths of 24 and 25 inches the two interpreters could detect an object below the surface, but they could not state with certainty that it was a marker. In depths exceeding 27 inches, the markers were not visible. These figures agree with observations made in the field during the reconnaissance phase of the study.

Table 10
Depths of Water at Which Markers Were Visible

Water depth (in inches)	Film	Scale	Marker visible
14	Aerecon Plus-X	1:12,000	yes
14	Aereographic Super-XX	1:5,000	yes

27	Ektachrome	1:5,000	no
*			

*Markers were definitely not seen in depths from 27 to 56 inches.

Discussion

The volume and accuracy of information varied between the types of vegetation, the scales of photography, and the experience of the interpreters, but not between the film materials used. A discussion of these factors may indicate some of the reasons for this variation.

Films

Color films have a greater potential for recording detail than panchromatic films because there are many more colors and hues than there are shades of gray (Colwell, 1954, and Ray and Fischer, 1957). Nevertheless, with the 11 types of vegetation studied, the only benefits obtained from the color materials were slight increases in accuracy when identifying pickerel weed stands, and a possible increase in accuracy of identifying silt.

All of the interpreters used the added clue of color when studying the color films, and on many of the color coverages, they stated that they were more certain of their interpretations. However, the scores did not reflect the supposed added certainty.

It is possible to obtain more detail on aerial photographs by using a camera equipped with a device to compensate for movement of the aircraft. Since this equipment was not available, it is quite possible that the full potential of the films was not realized. This is particularly true with the Aerecon film, which is designed to give maximum detail. The prints made from the Aerecon film had greater contrast than those made from Aereographic film. The added contrast seemed to make interpretation more difficult, but only small differences in scores were obtained.

Ektachrome transparencies were slightly over-exposed at the 1:20,000 scale and slightly under-exposed at the 1:5,000 scale. These differences in exposure did not appear to affect interpretation in general, but the low accuracy of identifying sweetflag on the 1:20,000 scale may have resulted from the over-exposure.

Color transparencies were more difficult to use, because extra equipment, such as a light table and a mirror stereoscope, were necessary to view them properly. In this study a simple lens stereoscope was used, but the field of vision was small and considerable manipulation of the photographs was necessary. Since the color transparencies were the original film, they could not be replaced if damaged or destroyed. Therefore, caution was necessary when they were used.

As the color negative film is comparatively new, considerable difficulty was encountered in obtaining prints from it. The results from the interpretations of this material did not vary significantly from those from the other films. However, the accuracy of identifying vegetation types on the 1:12,000 color prints was 4 per cent greater than the accuracy obtained with the other 1:12,000 photography.

Scales and experience of interpreter

Except for differences in accuracy of interpretation associated with plant species or types, the major variables seemed to be the scale and

the experience of the interpreter. These two closely related variables are compared in figure 3.

Differences in the overall accuracy of interpretation for the four levels of interpreter experience are apparent. Since the photographic images were relatively easy to memorize, the differences were probably caused by variations in experience with marsh ecology. Interpreters with a greater knowledge of marsh ecology used more deductive reasoning (interpretation) when making their decisions, while the interpreters with less knowledge of marsh ecology relied on identification of photo-

Figure 3
Relation Between Interpreter Experience and Scale in
the Identification of Marsh Vegetation

graphic images (photo reading). Both student interpreters were able to devote much more time to studying marsh ecology through the training aids than were the experienced interpreters. The higher scores obtained by the students seem to reflect this additional study. The experienced interpreters relied only a limited extent on ecological information, as obtained in a brief study of the training aids.

While developing the classification system, trial interpretations and field verification were possible for interpreter A. His higher scores at all scales indicated that these field verifications contributed to accurate interpretation. Interpretations made by the test personnel undoubtedly would have been more accurate had they been able to verify some of them in the field.

The photo interpreters with experience or training in marsh ecology interpreted nearly as accurately on the 1:12,000 photographs as on the 1:5,000 photographs. This indicates that, to some extent, more field experience is necessary to use smaller scales of photography. The wide range of accuracies obtained by the interpreters when using the 1:20,000 photography further supports this premise; also the interpreters without actual field experience stated they were uncertain of many identifications on the 1:20,000 photography.

Smaller differences in height were discernable with each increase in scale. With the exception of round stem bulrush and three-square bulrush, the heights detected in the vegetation corresponded with the calculated heights for each scale (figure 4). Apparently, leaves or inflorescence on the upper parts of the plants are necessary for height perception, and the leaves and/or inflorescence of round stem bulrush and three-square bulrush were not sufficient.

Photographic images

The physical structure of the plant is probably as important in producing the photographic images as the tone or color of the plant. The marsh types studied can be discussed in groups by physical structures.

Leafy-topped rushes and grasses

The characteristic images produced by leafy-topped rushes and grasses are medium in tone. The heights of these stands are evident. The stands of river bulrush on the photographs of Merrymeeting Bay (appendix I), and the stands of cane (*Phragmites communis*) on the photographs of the Delta Marsh, Manitoba⁹, are examples of such leafy-topped plants. Wildrice stands at maturity may produce images with light tones. Those at Merrymeeting Bay were usually flattened down

⁹ Aerial photographs of the Delta Marsh, Manitoba are included in appendix I to further illustrate some of the photographic images of marsh plants.

Figure 4

Calculated Height Perception for Photographic Scales
Employed in This Study

by wind and tidal action so that no height was obtained from their photographic images.

Bulrushes without leafy tops

The most characteristic feature of the images of round stem bulrush is that height cannot be determined unless the stand is extremely dense or the photography is of very large scale. The edges of the stands are usually indistinct. The tone is dark and the image appears to be formed by the shadows within the stands. The presence of shallow standing water darkens these images considerably; when the water is two feet

or more deep, as with hard stem bulrush (*Scirpus acutus*), the plants frequently cannot be seen. Stands of three-square bulrush produce images which are very diffuse and somewhat reticulated. The denser three-square bulrush stands tend to be confused, in the interpretation, with round stem bulrush; also, due to lack of height perception, both of these types are frequently confused with submersed aquatics.

Plants with sword-shaped leaves

Sweetflag stands have very dark tones (darker than bulrushes) and images with very sharp edges. The flattened, upright leaves produce more shadow than the round stem or three-square bulrushes. The height of these stands is discernible on large scale photography. Cattail (*Typha latifolia* and *Typha angustifolia*) stands which are labeled on the Delta photographs (appendix I) also have sharp, black images which are uneven in height. Several stands of giant burreed (*Sparganium eurycarpum*) were examined in the field and on the aerial photography. Their images were darker than the round stem bulrush images, but sharp edges were not discernible.

Plants with large flat leaves

Both yellow waterlily and pickerel weed stands produced granular photographic images and tones which were similar to the tone of the individual leaves. The reason probably is that these large-leaved plants reflect more light than most plants with small leaves. The granular image results from clusters of leaves. Height of these stands is evident only on large scale photography. In this study yellow waterlily and pickerel weed could usually be separated by differences in tone and texture.

Submersed aquatic plants

The most characteristic image features of submersed aquatic plants are lack of height and extreme variability in pattern and tone. At Merrymeeting Bay most of the submersed aquatics were exposed at low tide. Their images varied from solid or patchy areas to diffuse reticulations. When reticulations were present they tended to line up with the current or in the direction that the tide receded. Some tone differences were evident on all scales. Beds of submersed linear-leaved arrowhead (*Sagittaria spp.*) were always lighter. On 1:5,000 photographs several tones were evident in beds of submersed aquatics.

The depth to which one can see into water on aerial photographs influences the amount of submersed aquatics that can be observed. Several submersed aquatic beds at Merrymeeting Bay were not visible except on photography made at the lowest stage of tide. Species which grow to the surface are more likely to have discernible images. On the

Delta photography (appendix I), several beds of submersed aquatics with surface growth are labeled. If the three stereo pairs of Delta photographs are examined, it will be noted that the water in certain areas is lighter in tone and that beds of submersed aquatics are easily seen. These differences are due to planktonic algae. A light wind may also indicate beds of submersed aquatics with surface growth, because such growth disrupts the patterns which the wind ripples produce.

Duckweeds and algae

Duckweeds (*Lemna spp.*) have a high light reflectance and produce images with light tones and no height. As duckweeds are not rooted, they are found in places which are protected from the wind. Filamentous algae, which grow at the surface in stagnant waters, also reflect much light. Study of the Delta photography indicated that these duckweeds and algae are likely to be confused. Also, because of their light tones, such areas may be confused with sand and mud flats. Duckweeds are annotated on the aerial photographs of the Delta marsh in appendix I.

Sand and silt

Images of sand are very light in tone and usually have a characteristic pattern. On bars the pattern is rippled and wave-like, and along shore lines the pattern is smooth. Certain areas in this study were elected to test confusion of sand images with those of flattened, dense wildrice. Little confusion was noted.

On the Merrymeeting Bay photographs, silt images were usually medium in tone and with or without a pattern. If a pattern was present it consisted of diffuse reticulations that paralleled the channels or bays. These reticulations resulted from areas of fine sediments on the surface of the silt. Silt or mud flats have a very high light reflectance on some photography; consequently, they appear very light in tone and can be confused with other light-toned images.

Mixed vegetation

Two kinds of mixtures were evaluated in this study. One was a rather coarse mixture of vegetative types, such as round stem bulrush and pickerel weed, and the other was the high tide zone, a finely integrated mixture of many species.

In the mixtures of types the correct identity was stated more often when the tones of the components were dissimilar. Mixtures of similar tones tended to be identified as one of the components.

The high tide zone was composed of many species, none of which could be recognized. The tone and texture were both very even, prob-

ably because of the finely integrated nature of the type. The white top sloughs on the Delta photographs are also examples of finely integrated mixtures.

Review of literature

The use of aerial photographs for the study and mapping of wetlands is not new. They have been used to identify these areas and to map the broad ecological zones within various kinds of wetlands. Some of the previous studies have recognized species of plants on aerial photographs as indicators of the ecological zones. However, no quantitative evaluation of such interpretation was found in the literature.

Several workers have described the use of aerial photographs in mapping vegetation of marsh areas. In Massachusetts, MacConnell and Garvin (1956) recognized five types of fresh wetlands and one of salt marsh. Their classification is based in part on the wetlands classification which was set up by Martin, *et al.* (1953). Dalke (1937) stressed the value of aerial maps and ecological principles in mapping vegetation, and described the mapping of ecological zones such as submersed vegetation, floating leafed species, and also rushes and cattail. Nicholson and Van Deusen (1953) recognized six types of coastal marshes in Maryland. However, the aerial photographs were used chiefly for delineating major plant zones, and identification of the plant composition of these zones was made in the field. O'Neill (1953) studied the vegetative types in the Chesapeake Bay area. He constructed a set of keys for interpreting ecological zones in coastal marshes during the four seasons of the year. In the Wetlands Survey of Maine (1954) aerial photographs were used primarily for locating marsh areas. Zohari, *et al.* (1955) studied tone differences on aerial photographs of papyrus stands in the Hula Marshes of Israel. They were unable to find a relation between density of plants and tone of photographic images.

Tundra and range vegetation have some photographic characteristics which may apply to marsh vegetation. Churchill (1951) studied aerial photographs of tundra vegetation. He found considerable variation in the photographic images and was unable to establish the reliability of using aerial photographs of tundra vegetation. The Manual of Photogrammetry (1952) indicates that species composition and density of range vegetation can be mapped by using aerial photographs in part and field identification in part. Colwell (1946, 1948) demonstrated that several kinds of tropical crops and natural low vegetation could be identified on aerial photographs.

Cameron (1950) identified seaweed beds off the coast of Nova Scotia on panchromatic and color photography. He recommended pan-

chromatic film with a green filter for general survey procedure. With this film/filter combination, seaweed beds in water up to four fathoms deep could be mapped. In low-altitude continuous-strip photography he found color transparencies superior to panchromatic prints. Several other comparisons of film material have been made; however, none of these were on photographs of marsh vegetation. Young (1953) counted plots of trees using infra-red prints, infra-red positive transparencies and color transparencies and found no significant differences between films. Shulte (1951) evaluated infra-red prints, panchromatic prints, and color transparencies for identification of tree species in southeastern Canada. He found that infra-red was superior to, and panchromatic about equal to, color transparencies. Spurr and Brown (1946) also found that infra-red was superior to panchromatic and color positive films for tree identification, but that color, when properly processed, was superior to panchromatic.

Young (1953) compared the accuracies of counting trees on several scales of photography and reported a 20 per cent overall increase in accuracy between 1:15,840 and 1:3,500. Spurr (1948) reviewed the scales of photography which are commercially available and recommended 1:15,840 for general forestry work, and larger scales for more detailed interpretation. On the basis of accumulated research information, Stone (1956) suggested that species of brush and grass, and specific crops could be identified at scales larger than 1:10,000.

The military photo interpretation schools recognize that a familiarity with the subject being interpreted is an aid to accurate interpretation (Gardner, 1948). Military photo interpreters are trained in a series of phases, each of which covers one subject. During a particular phase a student learns what the subject looks like on aerial photographs, and he also becomes familiar with it on the ground.

Pomeroy and Cline (1953) studied the preparation of soil maps by various persons. They found that if a person had no field experience in the area being mapped his accuracy was lower than that of a person with field experience. They also found that as areas increased in complexity the accuracy of mapping decreased. DeLancie, *et al.* (1957) also evaluated the factor of experience in their study of photo interpretation keys. When interpreting naval vessels and abstract objects, inexperienced photo interpreters scored as well as the experienced photo interpreters, but the experienced photo interpreters had a higher accuracy when interpreting vegetation.

Appendix I

Aerial Photography

Six stereo pairs of aerial photographs illustrate some of the problems discussed.

The first three sets are panchromatic prints of a portion of the Merrymeeting Bay study area. Some of these areas were used in the interpretation tests.

The last three sets are panchromatic prints of the De'ta Marsh, Manitoba. While they are not a part of this study, they have been included to supplement the illustrative material. Information concerning these was obtained by the author while assisting S. T. Dillon in field work on the area in 1956.

The photographic images, which are separated by 2 1/8 inches, allow stereo vision for the average range of interpupillary distances.

Annotations used on the photography are as follows:

Wildrice — Wr	Submersed aquatics — Sub
Round stem bulrush — Rs	Sand — Sand
River bulrush — Rb	Silt — Silt
Sweetflag — Sf	Duckweeds — Du
Yellow waterlily — Wl	Phragmites (cane) — Ca
Pickereel weed — Pw	Cattail — Ct
High tide zone — Ht	White top sloughs — Wt
Three-square bulrush — 3 sq

Appendix II

Descriptions of the Eleven Classifications of Marsh Vegetation Interpreted

Type: Yellow Waterlily (W1)

Photographs: A medium-dense stand just as the tide was flooding.

Description: In addition to the waterlily or spatter dock, this type contains occasional stems of round stem bulrush, three-square bulrush, submersed aquatics, and wildrice. It grows in sparse patches on exposed areas, as medium to dense patches in other vegetation, and as extensive beds in protected coves. The soil is usually silt or sandy silt, and it is found in association with all of the types except sand.

Image Characteristics: This type has a very granular image which is green or yellow-green on color films, and a medium gray on panchromatic films. Height is evident only at scales of 1:5,000 and the granular texture may not be noticed at scales of 1:20,000.

Remarks: The round or lobate patches of this type, which occur in most situations, and the large unbroken stands of waterlily suggest that this is a very successful species on the study area.

Type: Pickerel Weed (Pw)

Photographs: Sparse stand on silt flat (left). Dense stand (right)

Description: Pickerel weed usually occurs in pure stands, but there may be a few submersed aquatics present. It seems to be a pioneer species, for it grows regularly on open areas of silt as lobate patches and along edges. The soil is usually silt, and it is associated most often with three-square bulrush, submersed aquatics, round stem bulrush, sweetflag, and waterlily.

Image Characteristics: Pickerel weed has a slightly granular image and is usually medium to dark green on color photography, and medium gray on pan-chromatic photography. The edges of stands are usually distinct.

Remarks: Pickerel weed seems to be a pioneer type, because it is frequently found on open areas of silt or edges, and it is seldom found in dense vegetation.

Type: Three-square Bulrush (3 sq)

Photographs: Sparse stands of three-square bulrush on silt. Notice submersed aquatics.

Description: Frequently mixed with submersed aquatics and always grows on areas of open silt or along edges. This type does not grow in dense stands.

Image Characteristics: Indistinct pale green areas on color films, and indistinct medium gray areas on panchromatic films. This image is very "fuzzy," but it may be quite distinct in some stands near the high water areas.

Remarks: Very hard to separate from sparse submersed aquatics, or silt.

Type: Sweetflag (Sf)

Photographs: A dense clump of sweetflag growing on an open silt area.

Description: Sweetflag usually occurs in dense, pure stands, but occasionally stems of wildrice, round stem bulrush, three-square bulrush, and submersed aquatics are found. It is found most often with silt, pickerel weed, round stem bulrush, and waterlily, and it grows on silty soils.

Image Characteristics: The texture is smooth and the edges of the stand are sharp. This is the darkest image (dark green or black) found on any of the photography. Height is not visible at scales of less than 1:5,000. Stands are mostly round or lobate, but they may be reticulate.

Remarks: Sweetflag grows most thriftily in open areas where its stands are round or lobate. Frequent "doughnut" shaped stands indicate that it creates conditions in the center that are unfit for its own growth. In areas of mixed dense vegetation, sweetflag stands are usually reticulate or irregular in form.

Type: Submersed Aquatics (Sub)

Photographs: Dense beds of claspingleaf pondweed (*Potamogeton perfoliatus*)

Description: Submersed aquatics grow on silty soils and are always found in the water or on areas that are exposed the least by low tides. This classification includes all the submersed species found on the study area. The types most frequently found with submersed aquatics are silt, three-square bulrush, and round stem bulrush.

Image Characteristics: Extremely variable. Occur as patches, strings, or solid beds. Color (green) and shades of gray are variable. Frequently there is a reticulate pattern with most lines running in the direction of the tide.

Remarks: Association with water or low tide is a definite aid in interpreting submersed aquatics. Variations in color suggest some species identification may be possible.

Type: Round Stem Bulrush (R_s)

Photographs: Dense stand of round stem bulrush

Description: Occurs mostly as pure dense stands in protected areas and as sparse stands in exposed areas. Frequently stems of wildrice are found in and near round stem bulrush stands. This is the plant at exposed sandy edges. It grows on either sand or silt and is usually associated with wildrice, submersed aquatics, silt, sand, and river bulrush.

Image Characteristics: The most characteristic feature of round stem bulrush images is that height cannot be detected at any of the scales tested. The images are blotchy and dark and have indistinct edges. Dark green on color, and dark gray on panchromatic.

Remarks: Occasionally many plants in a stand will be bent over, and heights of such stands can be seen.

Type: High Tide Zone (Ht)

Photographs: General and detailed views

Descriptions: This type is the "shallow fresh coastal marsh" described by Shaw and Fredine (1956). It always occurs near the high tide limit along shores. Plants composition is variable, but it usually includes scattered wildrice, three-square bulrush, and spike rush (*Eleocharis* spp.). Soil type is either sand or silt.

Image Characteristics: Smooth tones of gray on panchromatic photography, and amber colors on color photography indicate this area.

Remarks: Very easily interpreted because of location and color. Widely different plant compositions in this area produce similar photographic images.

Type: Wildrice (Wr)

Photographs: Dense stands of wildrice (prostrated by the tides).

Description: Usually occurs as pure dense stands and, as on this photography, it is usually prostrate. Typically found in protected coves with soft silt bottoms. The high tide zone and yellow waterlily are most often associated with wildrice.

Image Characteristics: Images usually have no height, or the rice appears to lean on other vegetation. Wildrice appears white on panchromatic photography and yellow-green or yellow on color photography.

Remarks: Some areas of standing wildrice may be present. These areas have light colored, uneven images and the height is evident.

Type: River Bulrush (Rb)

Photographs: A patch of river bulrush within a larger stand of round stem bulrush.

Description: Grows in dense stands. Usually in areas of round stem bulrush, waterlily, and wildrice. Usually the river bulrush stands do not have any other species mixed with them. The soil material is commonly silt.

Image Characteristics: The leaves are primarily at the tops of these plants and they produce a very noticeable height on the photographic image. The texture of the photographic image is smooth with occasional pits.

Remarks: Difficult to see height on 1:20,000 photography, but very definite heights on 1:5,000 and 1:12,000 scales. Always occurs within a vegetated area.

Type: Silt (silt)

Photographs: Stereo pair of a typical silt flat showing blotches or streaks.

Description: This type consists of silt flats barren of vegetation, or with extremely sparse growth. Commonly found near water and with three-square bulrush or submersed aquatics.

Image Characteristics: Smooth in texture. On color silt appears brown or purple-brown, and on panchromatic photography it has a medium gray tone. Reticulations are often present, and they parallel the channels.

Remarks: When silt areas have considerable sand present they may appear very light.

No Photographs Available

Type: Sand (sand)

Photography: None

Description: Areas of granular quartz sand, which support little vegetation except round stem bulrush and three-square bulrush. Usually bare sand is found along the edges of channels or in open water areas where there is considerable wave action.

Image Characteristics: Very light due to large amounts of reflected light. On panchromatic photography the sand areas are usually white, and on color they are pale yellow-brown. Frequently has scalloped surfaces due to wave action.

Remarks: Found only in areas with strong currents.

Appendix III

Description of the Line Intercept Sampling Method

In an attempt to describe accurately the plant composition of the test areas, the following modification of the line intercept sampling procedure was employed.

Materials:

1. One steel rod ten feet long and $\frac{3}{8}$ -inch in diameter, on which each 1-foot, and each 1/10-foot unit was marked (see photograph, page 53).
2. Two wooden stakes four feet long with adjustable loops to support the ends of the rod.
3. Mimeographed cards on which to record data (see sample card, page 53).

Procedure:

The location of the rod within each area to be sampled was selected randomly. The rod was passed through the vegetation, or over it, and supported at both ends by the stakes. Care was taken not to alter the position or composition of the plants prior to recording data.

Each species that occurred above or below a 1/10-foot unit was marked "one." Data were recorded for each 1-foot unit, and totaled for the 10-foot sample. The height of the rod above the ground was adjustable to three feet, but frequently data for taller species had to be estimated. Visual examinations were made in the areas around the samples, and any species not included in the samples were recorded. Estimates of density (sparse, medium, and dense) were also made for each species.

The information obtained was species composition, an approximation of the per cent of ground covered by each species, and an index of frequency.

Advantages of Method:

1. Rapid to use (about five minutes for a 10-foot sample).
2. One person can use it effectively.
3. Suitable for plants of different heights.
4. Does not disturb sample area prior to recording data.
5. Results vary little between observers (five trials of two persons averaged 1 per cent difference).

Disadvantages of Method:

1. Per cent of ground covered is exaggerated for some species which occur sparsely.
2. Per cent of ground cover is exaggerated when species such as wildrice are prostrate.
3. Estimations have to be made for the taller species.

Appendix V

Results of a Survey of the Costs of Aerial Photography

Cost of aerial photography is based primarily on the length of time the photographic aircraft is in the air. Other factors which affect cost to a lesser extent are flying weather, work load, season, size of area covered, type of film material, and exactness of specifications.

In January, 1958, a letter-type questionnaire was circulated to 12 aerial photographic concerns in the United States and Canada to obtain general information on costs and capabilities. Seven of these letters were answered and returned. Costs are extremely variable and change particularly with time; the information here presented should be evaluated accordingly.

Estimates of costs for photographing 36 square miles with 1:20,000 panchromatic film varied from \$285 to \$1,440. Most of the estimates were between \$500 minimum and \$1,000 maximum.

The costs for photographing one square mile at the same specifications were also requested. These estimates varied from \$50 to \$350 if flown at the photographer's convenience, and from \$75 to \$500 if flown at the customer's convenience.

Most of the concerns indicated that costs vary by season, flying weather, and work load.

A general rule has often been stated that "as scale is doubled cost is quadrupled." Two of the concerns agreed with this rule. The other five concerns estimated doubling or tripling of cost as scale doubled. Five of the concerns indicated that they could take aerial photographs on color transparencies, and four indicated that they could expose and process the color print material.

Estimates of the additional costs for color photography varied from a flat rate of \$50 to \$100, or 20 to 100 per cent more than panchromatic. It should be pointed out that with large flying contracts, the extra cost of color is absorbed by the large size of the job.

In summary, the primary factor in costs of photography is the length of time the aircraft is airborne. Costs can be expected to double, triple, or quadruple for each doubling of scale. Costs for color photography are higher when small amounts of photography are taken.

Information Received on Seven Letter Questionnaires to
Aerial Photographic Concerns

1. What is your estimate for flying 36 square miles of stereo coverage with the following specifications?
 - a. 1:20,000 scale
 - b. panchromatic film
 - c. six inch focal length
 - d. within 100 mile radius of your airport
 - e. normal amount of overlap, number of prints, mosaics, etc.

Maximum price	Minimum price
\$1,440	\$900
1,200	750
1,000	750
1,000	500
750	500
500	350
285	250

2. What will the cost be to cover one square mile at the above specifications?

At your convenience	At the customer's convenience
\$ 75	\$100
200	350
350	500
200	500
75	75
100	200
50	110

3. Will the cost vary with work load (yes 5, no 2), season (yes 6, no 1), and flying weather (yes 7, no 0)?
4. A general rule has been stated that as scale is doubled cost is quadrupled. Do you agree with this statement (yes 2, no 5)? If not, can you cite a figure? Doubled 3, Tripled 1, Doubled to tripled 1.
5. Does your firm have the capacity to expose and process the following?
 - a. color positive aerial photography, i.e., Ektachrome
yes 4, no 2, limited 1
 - b. color negative materials, i.e., Ektacolor
yes 4, no 3

6. How much more would the 36 square miles of coverage mentioned in question No. 1 cost if flown in color positive aerial photography?

Answers:

no figure available

20 per cent

we don't do color photography

1.5 to 2.0 X

\$50 maximum

\$100 maximum

Appendix VI

Suggestions for Obtaining and Interpreting Air Photos of Marsh Vegetation

Use of existing photography

Practically all of the United States and large portions of Canada have been photographed from the air one or more times; prints of most of this photography are available at prices much below that of new material. When planning to obtain photographs of an area, one should consider these prior coverages. Frequently, the date, season, or scale of prior coverages is unsuitable, but in most cases some information can be obtained and in a few cases prior coverages are very useful. The table on page 62 contains a list of scales commonly available, descriptions of what the photography is used for, and some information as to how extensive it is.

Examination of vegetation

If existing photographic coverages are not available or not useful, new photography may be considered. Before ordering new photography, the structure, color, and tones of the vegetation should be examined in the field. These comparisons may indicate how useful a new photographic coverage would be.

In Merrymeeting Bay, vegetation at distances of 100 yards appeared either as patches of one species or mixtures of many species, which were mostly unidentifiable. On aerial photographs of the same area the "patches of species" could be recognized, but the mixtures could only be recognized as such.

It is doubtful whether areas of very sparse plant growth can be recognized on aerial photographs.

Selection of film

Panchromatic aerial photographs were less expensive, more easily obtained, and as useful for interpretations of this type as the other three films. Based on the results which Cameron (1950) obtained with seaweed, it may be advisable to employ a green filter when areas of submersed aquatics are photographed. Also, it may be advisable not to employ haze filters when water penetration is desired, as they tend to darken images of water.

Selection of scale

When selecting photographic scales, the information desired, the

experience of the person who will use the prints, and the costs¹⁰ of the photography should be considered. For mapping or non-quantitative evaluations of marshlands, 1:20,000 photography is adequate. It is an excellent scale for studying the broad ecological relationships within and between marshes, because nearly nine square miles can be viewed on each photograph. Most mapping of wetlands has been with photography of this scale. For detailed identification of plant species, scales of 1:15,000 or larger are advisable. In this study, interpreters who were familiar with marshes interpreted 1:12,000 photographs nearly as well as 1:5,000 photographs. For inexperienced personnel, the largest scale possible should be obtained.

Time of photography

When planning aerial photography of marshlands, or when using existing coverages, the date, time of day, and water level should be considered. The photographs of Merrymeeting Bay were taken at near maximum plant growth in late summer. Although there were no suitable coverages of different dates for comparison, these seemed to provide adequate information. Comparison of the Delta photographs made in spring and late summer (appendix I) indicates that interpretation is much easier with the latter. In the spring, *Phragmites* growth shows three different tones, and in summer it appears as one tone only. Likewise, in the spring, cattail and round stem bulrush stands are very light and hard to separate, and the submersed aquatics have not developed sufficiently to be seen. The white top sloughs, however, are more evident on the spring photographs.

For many purposes aerial photographs are best taken at mid-day. For marshes it is suggested that they be taken in the morning or afternoon. Marsh vegetation does not produce extensive shadows, while those that are produced are useful in interpretation. Also, as the sun's rays approach an angle of 90° the reflectance from water and wet surfaces will increase. Morning photography is preferable, because haze and clouds are usually less.

When photography has to be timed for low tides, and the range is four to six feet, the time of photography should not be more than one hour on either side of low tide.

In this study the presence of water in and around stands of vegetation made interpretation much more difficult. Therefore, it is suggested that aerial photographs of marshes be taken at low water levels. Water level fluctuations which last over considerable periods of time change both the amount of and species composition of the vegetation. While aerial photographs may be an important means of measuring these

¹⁰ In appendix IV the results of a survey concerning costs of aerial photography are presented.

changes, analysis of vegetation on photographic coverages should be made with consideration of water levels and time of photography. A comparison of photographs on pages 40 and 41 illustrates long-term water level changes and their effects.

Interpreter training

An adequately trained interpreter can work more accurately, more rapidly, and will have more confidence in his interpretations than an interpreter with insufficient training. Results of this study indicate that training in the use of a stereoscope can be obtained easily and quickly; also, that some field training, which may be self-acquired, is necessary, regardless of prior experience. Experience and training are usually acquired during the steps in the selection of a satisfactory classification system, but each set of interpretations and field checks adds to this training.

A classification system

Before accurate and efficient interpretation of vegetation can be performed, a satisfactory classification system must be devised. The steps necessary are the same in all photo interpretation studies. They consist of; examination of photographic images and the corresponding objects, selection of a tentative classification, trial interpretations, and field checks. Usually, repetition of these steps is necessary. All of the types in the classification system should be those which can be identified on aerial photographs. The situation with respect to three-square bulrush, described in this study is a good example of a classification which should not be included.

Field verification

Since photo interpretation is an art as well as a science, some errors are unavoidable (Young, 1953). For information obtained by interpretation to be properly assessed, the errors must be quantitatively determined by a series of field samples.

In this study, the true identity of all stands of vegetation was known. Obviously, this cannot be done in practical applications, but a field sample consisting of a number of stands of each type can be identified, and the accuracy of the sample applied to the photo interpretation results.

Scale Equivalents, General Usage, and Availability* of Aerial Photography

Reciprocal fraction	Equivalent	General uses	Availability
1:5,000	1" - 416'	Detailed interpretation. Town planning.	Limited, usually small areas.
1:7,920	1" - 660'	Forestry, detailed interpretation.	Limited, usually forest lands.
1:10,000	1" - 833'	Agriculture - crops.	Limited
1:12,000	1" - 1,000'	Highway planning. Detailed soils studies.	Very limited
1:15,840	1" - 1,320' 4" - 1 mile	Agriculture, forestry mapping.	Extensive of Canada, United States, Alaska
1:20,000	1" - 1,667'	Mapping, Soil Conservation Service. General uses, agriculture.	Most available and widely used civilian photography
1:24,000	1" - 2,000'	Geological Survey Mapping	Available in states with current topographic mapping
1:31,680	1" - 2,640' 2" - 1 mile	Mapping, forest inventory	Extensive
1:40,000	1" - 3,333'	Mapping, reconnaissance	Extensive of U. S. usually old photos.
1:50,000	1" - 4,166'	Air Force Reconnaissance	Much of Alaska
1:70,000	1" - 6,333'	Reconnaissance	Parts of Maine

*Information concerning availability of coverages of particular areas is available from the Office of Map Information, U. S. Geological Survey, Washington 25, D. C.

Abstract

A survey of the state-of-the-art in the evaluation of natural terrain by earth-science techniques and measurement systems is presented in response to a need that existed for many years. This report considers the terrain as an envelope of the environment and all related parameters that are basic in an evaluation for relevant military applications such as unimproved landing areas, trafficability, site selection for operational facilities, terrain reconnaissance and surveillance, and target detection within a masked terrain complex. Methods of terrain-data acquisition, analysis, and evaluation and their limitations are reviewed. The status of research and development, specifying the gaps in technology, is summarized with accompanying conclusions. The report forecasts the requirement for an automated terrain-data acquisition, storage, and display system. Recommendations are suggested for further investigation to advance technology that will provide quantitative terrain factor values. A simplified matrix method of digitizing terrain data is described in the appendix as a necessary intermediate step to the computerization of pertinent data. Information pertaining to the classification of terrain data, field devices to measure bearing strength, and a visualized optimum remote sensing system is also given in the appendix. A glossary and a comprehensive bibliography are included.

Preface

Reliable methods for predicting terrain conditions on a quantitative basis are vital in the planning of military operations. In the past an equilibrium was maintained regarding terrain-classification and weapon-system capabilities, but recent and rapid advances in weapon-system technology have made present terrain-classification methods inadequate.

Chapter I (Introduction) of this report describes the problem and delineates the need for terrain information. Methods of analysis and performance prediction of military activity by considering the terrain parameters, criteria, and environmental effects on the proposed activities are contained in Chapter II.

Chapter III on Remote Sensing is a summary of airborne sensing methods used for rapidly obtaining terrain and related scientific data over vast areas of the world. This chapter also introduces the concept of incorporating all types of sensors into systems that would produce imagery depicting the properties of different terrain.

Terrain utilization is discussed in Chapter IV. Many of the applications demonstrate the value of applied geoscientific analysis and evaluation for superior terrain-engineering planning.

Research and development to improve non-contact sensing technology is discussed in Chapter V. Gaps in the science and methodology and the status of present objectives are summarized. Some of these objectives are site selection, determination of aircraft trafficability on natural surfaces, development of analytical techniques, and evaluation of the effects of climate and weather on materials and terrain conditions.

Conclusions and Recommendations in Chapter VI identify the gaps in the knowledge of techniques for terrain utilization, and suggest areas warranting further research to develop a capability for acquiring and using data in a faster response to existing technological and operational needs.

A Glossary of earth-sciences terminology is included for the benefit and quick reference of the lay reader. The References and Bibliography contain selected material from the voluminous literature of the scientific and engineering community.

The Appendices present detailed information to supplement the material in the body of the report.

EARTH SCIENCE APPLIED TO MILITARY USE OF NATURAL TERRAIN

I. Introduction

1. PURPOSE

The utilization of earth-science technology in determining the potential of practical military use of natural terrain could greatly enhance the global mobility of our military forces. The purpose of this report is to delineate these techniques to scientific, engineering, and military interests, and to present salient background information for use in further research or terrain appreciation. The contents may be used for specialized training programs, guidance in planning, engineering needs, and strategic and tactical situations.

2. SCOPE

This report presents significant information, with pertinent references, on the properties of natural terrain. It defines terrain and its primary parameters; evaluates methods of analysis and data-acquisition techniques; surveys the research and development status of science and technology pertinent to the solution of military environmental problems; and points out the deficiencies in our present knowledge. The report also recommends programs to eliminate many of the limitations in our earth-science technology, with emphasis on non-contact sensing of terrain.

(Received for publication 23 July 1969)

3. STATEMENT OF THE PROBLEM

The military concept of maintaining global capability requires sufficient and precise information on terrain and related environmental conditions. The records reflect many instances where the lack of proper and timely information resulted in critical loss of time, life, material, and tactical superiority. These include problems primarily in vehicle and aircraft trafficability, shore landings, and the construction of installations.

These problems are adequately summarized by the following quotation of Lt. General William B. Bunker, USA, Former Deputy Commanding General of the Army Material Command: "Mother Nature, in the guise of swamps, mountains and deserts or as blizzards, fogs, and blinding heat is the true immobilizer of armies."

Since time immemorial, commanders have sought an army that could move in concert--combat, tactical support, and administrative elements--over the same terrain and at the same speed. This challenge is not always met successfully when operating in complex terrain.

The lack of terrain data for large areas of the world is a serious handicap. The primary sources of information (reports, maps, photographic documentations, etc.) are inadequate for producing necessary detailed data. Subtle conditions of the terrain complex cannot be estimated from small-scale maps or from data in the inventory that are not suitable for efficient use by performance-prediction models. Rapid non-contact measurement techniques of terrain parameters are only supplementing, not replacing, the standard, slower, ground sampling and testing methods.

The classification of terrain for analogous studies is difficult even in well mapped areas of the world. The formulas for direct comparison of terrain parameters of construction materials; surface roughness; temperature and moisture content as a function of climate and weather; drainage and water supplies; vegetative cover; horizontal and vertical distribution of surficial materials; and the nature of underlying geologic formations are based on proper data acquisition.

Today, planners, strategists, and operations analysts are frequently forced to use information that limits their decisions to the generalized rather than specific effects of terrain on the various military activities. However, today, a delay of an hour or the incapacitation of a portion of the tactical force through an unanticipated environmental or terrain condition could comprise the difference between defeat and victory.

4. NEED FOR TERRAIN INFORMATION

Since man's activities are predominantly terrestrial, they are largely dependent on his efficient use of the natural environment. In the past, he operated on a

theory of superabundance of resources in the environment. It was assumed that his world contained unlimited areas in which to expand, resources to exploit, water to use or pollute, and time to plan for the future. There is now the sudden realization that these assumptions are not true; man must now economize his natural resources and use his manpower, equipment, and terrain more efficiently.

To fully utilize the environment, it is necessary to know the properties of the earth. This knowledge can only be gained by new scientific techniques. New instrumentation is required to permit rapid data acquisition by automated methodology.

Tactical requirements dictate the precise location of operations. The military need for terrain information is usually implicit, and not specified in the official requirements; however, it should be a prerequisite in the evaluation of any prototype weapon or proposed plan.

Pertinent terrain information is vitally necessary for tactical maneuver of ground forces, battle planning, aircraft navigation, target location and analysis, site selection of bases and airfields, strategic planning, and other uses. However, the acquisition of this information is frequently assigned a relatively low priority, and data needs are often obscured by the system approach to weapons development (Sturm, 1967).

1.1 Historical Review

From the time of Homer in 900 BC, the concern for the knowledge of terrain in the form of myth and legend has been described in the records of military campaigns. In the 16th century, Niccolo Machiavelli wrote:

"...and meanwhile learn the nature of the land, how steep the mountains are, how the valleys debouch, where the plains lie, and understand the nature of rivers and swamps. To all this he (the prince) should devote great attention. This knowledge is useful in two ways. In the first place, one learns to know one's country, and can the better see how to defend it. Then by means of the knowledge and experience gained in one locality, one can easily understand any other than it may be necessary to observe; for the hills and valleys, plains and rivers of Tuscany, for instance, have a certain resemblance to those of other provinces, so that from a knowledge of the country in one province one can easily arrive at a knowledge of others. And that prince who is lacking in this skill is wanting in the first essentials of a leader; for it is this which teaches how to find the enemy, take up quarters, lead armies, plan battles and lay siege to towns with advantage" (Machiavelli, *The Prince*, Florence, 1513).

History has not changed the basic concepts of land warfare. Although methods of warfare have become more sophisticated, the objective is still to dominate the territory of the enemy and destroy his will to fight.

The major contributions of earth science applied to the art of warfare have been in cartography, geography, military geology, and engineering.

4.1.1 CARTOGRAPHY

Maps were first developed about 900 BC as a guide to explore the earth's surface. The great conquerors of ancient and medieval time used crude maps in planning and conducting their campaigns. Throughout history, military conquest has stimulated mapmaking and aided science. By 150 BC, cartography combined the achievements of the scientist with those of the explorer and surveyor in presenting a picture of the physical characteristics of the earth's surface. Maps and charts developed into a major source of information for military purposes in the last half of the nineteenth century (Lobeck and Tellington, 1944, p. 1).

4.1.2 GEOGRAPHY

Aristotle founded scientific geography about 350 BC. Mapmaking and later exploration furthered the progress of advancing geographic knowledge until the first modern world atlas was published by Ortelius in 1570. The knowledge of world geography was increasing by the early 1900's, with the exception of the more remote regions (Strahler, 1963, p. 7).

4.1.3 MILITARY GEOLOGY

Terrain features have been used to the disadvantage of enemy forces since 900 BC. In 1826, geology was first applied to warfare in Germany, followed by the U. S. Civil War in 1864—although a number of isolated examples occurred in earlier history when rivers were diverted or mined in war. The first American military geologist advised the U. S. Army on varied terrain problems during the war in the Philippines in 1899. Many countries expanded their interest and application of military geology in the 1930's. The large military organization added a staff of geologists, geographers, and related skills to assist in the planning and conduct of their operations (Erdmann, 1943, p. 1177).

4.1.4 ENGINEERING

Since the first fortifications were designed and constructed in early history, engineering units assigned to all military organizations have been delegated the responsibility to overcome terrain hazards and erect structures to enable the troops and weaponry to combat the enemy more effectively. Such structures were roads, tunnels, bridges, fortifications, gun emplacements, airfields, and dams. Indigenous construction materials were used by developed resourcefulness. Mobile warfare introduced many new problems for engineering ingenuity to provide the required construction, repair, maintenance, and logistic support, particularly in large scale operations (Erdmann, 1943, p. 1176; U. S. Geological Survey, 1945).

4.2 Modern Technology

As war became more complex, the size and range of artillery, missiles, and small-arms fire expanded. The airplane introduced problems of air navigation and precision targeting and bombing. Aerial reconnaissance furnished a fast and easy means of obtaining timely information concerning terrain and the enemy's movements and methods of attack.

With the advent of mechanized warfare in World War I, and improved capability of aircraft and ground forces in World War II, the tactical use of terrain became more critical. Science and engineering developed the means to surmount the major obstacles and minimize the hazards.

The progress made in photo-mapping techniques since the mid-1940's has been phenomenal. The aerial camera has developed as one of the primary surveying instruments. Topographic maps and photographs have been the main source of information in the appraisal of terrain and environmental effects. Supplementary data were added by studying recent large-scale geologic, soils, climatological, and vegetation maps. The introduction of terrain models and diagrams reconstructed from maps and photographs was accepted as a standard procedure for showing details in realistic perspective to the military leaders (Coleman and Lundahl, 1948, p. 453).

Since World War II, the military has used earth scientists and engineers in collaboration with intelligence groups to solve problems relative to military use of terrain. The rapid solutions to terrain problems, the preparation of special maps, and the provision of other requested data to forward combat organizations by these men received widespread praise for their accuracy and value (Committee on Geophysics and Geography, 1953, p. 7).

Present research is developing methods of remote sensing from aircraft and extending such a capability to satellite altitudes. These methods will provide knowledge of global terrain to predict performance of pre-planned activities. Refinement of differentiated signals from active and passive sensors is improving the identification of all natural materials and their properties in a suitable display for efficient system interrogation.

Current technology permits (1) the selection of landforms to support aircraft operations; (2) the identification of areas possessing weak natural materials or structures susceptible to natural or induced landslides; (3) detection of disturbed foliage, vegetation, or other terrain parameters that could provide enemy camouflage; (4) determination of the hazards of ice and snow surfaces and permanently frozen ground features; (5) the location of natural drainage hazards, impassable routes due to flooding or damage; and (6) assessing site stability and the potential occurrence of disasters from catastrophic forces (Van Lopik, 1962, p. 776).

Earth-orbiting surveys, utilizing photographic sensors, offer a unique system for producing topographic and geologic maps. Maps at 1:1,000,000 or smaller could be produced from such data on a global basis. Although much of the surface mapped at 1:1,000,000 needs revision, it would be impractical to complete world-wide mapping at this scale or larger except by orbital remote sensing (Carr and Van Lopik, 1962, p. 6).

An airborne and orbital system would enable the transformation of all map, photo, and quantitized terrain data into digitized form at data bank centers for transmission to forward military units in a matter of minutes to hours. The convenience and versatility of aerial and orbital surveying, mapping, and sensing methods have only commenced to be exploited for use in modern warfare (Mays, Noma, and Aumen, 1965, p. 19).

5. PREVIOUS WORK

Since 1935, U. S. and foreign civilian and military agencies, universities, private companies, and research institutions have conducted intensive studies to develop methods for predicting terrain conditions for military, scientific, and commercial use. The primary federal agencies engaged in research on terrain problems are discussed in Appendix A.

The bibliographic references on the subject indicate the wide range of topical and geographical coverage and gaps in information. Many organizations concentrated on some of these gaps in response to military needs. Recent emphasis has been centered on the classification of terrain parameters from the interpretation of remote sensor data.

Since its founding in 1879, the U. S. Geological Survey (U.S.G.S.) has been one of the leading non-military federal organizations in the scientific study of the earth and use of terrain for military and civilian purposes. For over 150 years, the U. S. Coast and Geodetic Survey (USC&GS) has been making precise measurements of the earth and its waters. Many State agencies have been using earth science and related technology in the construction of airfields, roads, highways, waterways, and installations. State governments also participated jointly with federal agencies in the long-term mapping and locating of natural resources.

5.1 Department of Defense

Since World War II, over 37 DoD agencies have been involved in area analysis, environmental research, and programs related to terrain. Their common objective is to obtain knowledge of the physical and cultural environment in all parts of the world. Of the agencies involved, 13 are in the Air Force, 16 in the Army, and 8 in

the Navy, Advanced Research Project Agency, and Defense Intelligence Agency (DIA). The description of their work pertaining to terrain is beyond the scope of this report. See Appendix A for additional information.

5.2 Other Government Agencies

Eighteen other research groups are distributed largely among the Dept. of Interior, Dept. of Commerce, Dept. of Agriculture, Atomic Energy Commission (AEC), National Science Foundation (NSF), National Aeronautics and Space Administration (NASA), and the Dept. of Health, Education and Welfare. These agencies have been performing major efforts in environmental research and testing. DoD has frequently utilized their services.

BLANK PAGE

II. Terrain Study, Analysis, and Evaluation

I. INTRODUCTION

A study of the natural environment necessitates dividing the total complex into its separate parts. One of these parts-terrain-is as an aggregate of all physical and man-made features of an area. This aggregate includes an exclusive group of primary and secondary factors that characterize specific attributes of the terrain (AFM 88-53, p. 146).

The primary factors are: surface geometry and landforms, composition and engineering properties, vegetation, and hydrology.

The secondary factors are: cultural features and climate and weather.

Different combinations of terrain factors can have similar effects on some of man's surficial activities and have a varying impact on others. Terrain factors do not have permanent critical values for all types of activities. In many cases, a critical value (the point beyond which the activity cannot be satisfactorily performed) will change if it is even slightly modified in form, weight, etc. (Carr and Van Lopik, 1962, p. 3).

Terrain assessment by genetic and physical-attribute examinations can provide reliable information; such information, derived from contact, non-contact, and indirect methods, yields valuable performance-prediction data.

Present methods correlate field-test data and supplementary sources with analagous terrain areas, but most of the available global information is qualitative, not quantitative as desired. At best, the qualitative genetic approach is merely a substitute for detailed, directly measured terrain data (AFM 88-53, p. 124).

2. REGIONAL AND ENVIRONMENTAL ASPECTS

A knowledge of regional information is a necessary background to understanding and analyzing geologic, soil, vegetation, and implied engineering conditions. The characteristics of the local terrain in factor classes (a specific category within a terrain factor) are then determined. A comparison of the features in the region with the local complex reveals facts on materials and their surface and subsurface properties. Landforms, drainage and erosion patterns, and vegetation which can be identified are correlated with features which cannot be directly observed (Belcher, 1948).

Environmental conditions directly affect the existence, development, and alteration of terrain characteristics. The formation and sculpturing of landforms are controlled by the decay of rocks at the surface, the nature of the underground geology, the degree of weathering action, and the influence of the climate. An uneven surface is the result of etching by agents of denudation or deposition of transported materials. Thick, well-bonded-type rocks resist erosion and remain as hills, while the weaker materials form valleys. Running water transports soil and broken material, and the rock waste carried by the water scour and modify stream and river beds. Gravity and wind are other forces which remove material. Along the coastlines, waves undercut cliffs and blocks of rock fall into the sea. Waves batter the fallen blocks into sand, and the tides carry away the sand.

Soil is formed from rock wastes, shattered minerals, and organic matter. It comprises the outermost layer of the earth's crust, and its profile includes the decaying remains of plants and animals, a wealth of living organisms, the roots of living plants, and bacteria.

The environmental temperature and the composition of the rocks in an area determine the character of the soil in that area. Rock wastage is removed unless the climate is conducive to the growth of vegetation that binds the materials in the soil. Removal of vegetation can result in rapid soil loss, and glaciation can completely strip a region of all its soil (Thornbury, 1954, p. 68).

3. TERRAIN CLASSIFICATION AND METHODS OF ANALYSIS

3.1 Classification

In the classification of terrain, the characteristics are described in subjective and objective terms, and data on landform, microrelief, soils, rock, drainage, vegetation, and related properties are incorporated.

The current technology is limited in the quantitative classification of terrain properties for determining the critical values in terms of their effect upon specific military activities. Expedient classifications of the terrain components, based on data obtained from field observations and laboratory analysis, are largely qualitative on individual factors (Carr and Van Lopik, 1962, p. 2).

Qualitatively described terrain with a few measured factor values can provide an index of the regional terrain. Classification by this method is rated on a valid universality of application, degree of simplicity of measurements, repeatability of factor values, mappability or portrayability of data produced by other techniques, and completeness of data.

The most accurate appreciation of terrain is obtained by scientific analysis of the data and a determination of terrain-factor effects on activities. The primary categories used to describe terrain follow.

3.1.1 SURFACE GEOMETRY

Surface geometry is the measurement of the physical forms of features constituting the earth's surface. The basic components can be measured as slope, relief, distribution of topographic highs and lows, plan and profile configurations, and related dimensions.

Landforms that are primary surface features have varying external and internal characteristics, are in various stages of development, and change with environmental conditions. The major landforms are the plains, plateaus, hills and mountains. The secondary features are cliffs, valleys, lakebeds (playas), and alluvial fans (Leet and Judson, 1967).

Landform classification commonly utilized is based upon differences and similarities resulting from variations in the local relief and in the amount of land in slope. Mountains and hills have most of their land in slope and have moderate to high relief while plains and plateaus have surfaces that are predominantly level or gently sloping and have low relief.

There is great diversity in the surface features of the four major types of landforms, and differences within each type result from varied conditions that caused the formation of the original surfaces, the weathering and erosion that have been present, and the variations in slope and local relief.

3.1.2 COMPOSITION AND ENGINEERING PROPERTIES OF TERRAIN

The terrain is a reflection of the surficial (unconsolidated) materials and bedrock (consolidated) materials in an area. Since military operations are dependent upon the characteristics of the unconsolidated portion, that portion is emphasized in this report.

The entire thickness of unconsolidated material overlying the bedrock is considered to be soil. It varies in definition by geologists, agricultural engineers, construction engineers, soil scientists, and others. Several systems of classification are commonly used, based on characteristics and uses (See Figure B-1 in Appendix B).

3.1.2.1 Soil Properties

The properties of soil vary with its grain size, structure, moisture content, color, vertical position in a series of distinct layers in the profile, and geographical location. Soil is usually a mixture of varying proportions of particles of different sizes. Each component contributes its characteristics and properties to the composite mixture.

(1) Profile

Many processes of formation occur as soil is formed from disintegrated particles of the earth's crust or parent material. Air and water enter the spaces between the particles, organic matter mixes with the particles, and the soil-formation process begins. Definite layers develop near the earth's surface, and these layers (horizons) differ chemically and physically. A vertical cross-section of these horizons constitutes the soil profile (Figure 1).

From the surface downward, four horizons are recognized and are identified by the letters A, B, C, and D. The upper layer, or A-horizon, is the zone where organic matter accumulates on the surface and where the semi-decayed plant and animal material or humus is found. This is the layer from which water soaking into the ground may remove material by either chemical or physical action. The B-horizon, the second layer, is the zone where material removed from above accumulates. It is usually composed of finer particles and forms a more compact substance than the layer above. The C-horizon consists of broken-up fragments of the parent material. The D-horizon is the underlying, unaltered parent material. Figure 1 compares a typical pedological soil profile with an engineering profile.

THEORETICAL SOIL PROFILE

*Process of water leaching downward through A and B horizons.

**Process of accumulating surface minerals through leaching upward, produced by evaporation in areas of low rainfall causing moisture to be toward the surface.

†Members of great soil groups

COMPARISON OF PROFILE FOR PEDOLOGICAL AND ENGINEERING PURPOSES

Figure 1. Soil Profile With all Horizons Present for Pedological or Engineering Interpretation

A typical profile is shown as follows:

<u>Horizon</u>	<u>Thickness</u>	<u>Range</u>	<u>Term</u>
A	10-12 In.	2 In. -4 Ft	Topsoil
B	10-12 In.	4 In. -8 Ft	Subsoil
C	Variable	Variable	Mother Soil or Parent Material in Broken Frag- ments
D	Variable	Variable	Underlying, Unaltered Rock Stratum

(2) Texture

The texture of a soil determines its ability to absorb water, heat, and air and its amenability to plant growth. The texture of a soil reflects the predominance of one size of particle or composite mixture of sizes imparting its peculiar properties. The common classes of texture are sand, silt, and clay that vary in size from diameters of 1 mm in coarse sands to a fraction of a millimeter in clays, as seen in Figure 2. Soils may include particles of organic matter.

Individual grains of sand can be distinguished, and they feel gritty to the fingers. Silt particles are difficult to observe, but they feel and look like flour. Clay particles cannot be seen without a microscope.

(3) Structure

The arrangement of a group of particles in a soil is referred to as its structure. A soil tends to be composed of units resembling a geometric-type figure. In sandy soils, the particles do not adhere. Clay forms into lumps or clods. In some soils, the particles combine into rounded aggregates of varying size. The structure of a soil indicates its capability of cultivation.

(4) Color

Color is the most easily observed and significant soil characteristic. It reflects the physical and chemical processes that formed a soil, it may be an indication of its fertility, and it differs with time, location, moisture content, and temperature. The apparent color may demarcate different major soil groups of the world and the limits of each soil horizon. Dark soils are better absorbers of solar radiation than those of light color and tend to be warmer, depending upon the circulation of air and water in them.

Soil colors range in shades or tints from white to black. The most common are dull shades of red, rust, brown, gray, or yellow. These colors represent variations in degrees of hydration and intensities of the oxides of iron. In humid regions,

Figure 2. Common Systems of Measuring Particle Size of Soil

a whitish color may indicate a lack of iron, but in arid regions, this color may denote a concentration of alkalinity or soluble salts and a lack of iron. Black and dark-brown colors often denote a high content of organic matter. Reddish brown is high in iron content, but yellow, brown, and mottled colors of them indicate a lack of iron in the soil constituents or poor drainage of the soils.

(5) Water Content

Gravitational, capillary, and hygroscopic water are the three types of moisture in soils. The type and percent of water in a soil have a great influence on the performance and value of a soil as a subgrade material. Excess moisture often reduces the bearing strength and adversely affects other properties of the soil (Strahler, 1963, p. 439).

(6) Soluble Salts

It is important that the presence and type of soluble salts in a soil be determined, because of their possible deleterious effects on construction materials. Also, soluble salts in a soil indicates that its engineering properties may change in the presence of percolating water.

(7) World Soil Types

Contrasts of topographic relief, parent earth material, climate, and vegetation produce a wide variety of soil types that are difficult to accurately classify on a world-wide basis. However, by classifying broad categories of undisturbed soil types as zonal soil groups, well-developed soil profiles can be established for analogous comparison with regions of similar climate, vegetation, and parent material.

3.1.2.2 Engineering Properties of Soils

The combination of internal friction, cohesion, compressibility, elasticity, capillarity, and permeability properties determines the suitability of soils for engineering use. These properties are influenced largely by the soil type and by its gradation, moisture-density relationships, and composition (Terzaghi and Peck, 1948, p.3).

(1) Structural Strength

The load-supporting capacity of a soil varies considerably with its moisture content and density. Methods for determining the strength of soil range from the use of complex formulas and empirical design criteria to controlled field and laboratory tests. Specialized training and experience are required to evaluate a soil for a specific use at a particular location. General estimates of the strength of various soil types can be obtained from published data, but for large structures, field-test data on the entire foundation area are required (Leggett, 1967, p. 1449).

3.1.3 VEGETATION

Vegetation is a prominent feature of terrain and has a great influence on military operations since it affects mobility, concealment, observation, and construction (Carr and Van Lopik, 1962, p. 56; Finch et al, 1957, p. 483).

For terrain analysis purposes, vegetation cover is subdivided into three major categories (Figure 3):

- a. Dimension - this includes height, crown shape, stem diameter, and root and stem variations.
- b. Physical Properties - the degree of woodiness, deciduousness, leaf characteristics, and spininess.
- c. Distribution - the spacing of stems, coverage of canopy, and arrangement of plants.

Vegetation may serve as a source of construction material, fuel, water, or food. It also is an indicator of climatic conditions, soil type, moisture content, drainage, and other surface and subsurface characteristics which are helpful in explaining the differences between terrain.

3.1.4 HYDROLOGY

A body of water is one of the main terrain factors, and its shape, size, distribution, moisture budget, and dynamic properties are factor classes. Other hydrologic information regarding terrain includes flooding susceptibility and controls, tidal variations, local drainage, and climatology (Strahler, 1963, p. 439).

The water supply in an area is dependent upon the sub-surface structure and materials and the amount, seasonal distribution, and type of precipitation in that area.

The total of all the moisture on or near the earth's surface and in the atmosphere does not vary widely from year to year, but exists in a giant circulatory system known as the hydrologic cycle. The cycle originates primarily with the waters of the oceans and seas that cover about three-fourths of the globe.

The occurrence and migration of subsurface water and the semi-permanence of natural water bodies are based (see Figure 4) on the following sequential processes:

- a. Evaporation of water from large water bodies.
- b. Condensation to produce cloud formations.
- c. Precipitation of rain, snow, sleet, or hail upon land surface.
- d. Dissipation of the rain or melted solids by direct runoff into lakes and streams, by seepage or infiltration into the soil and underlying rock formations, and by direct evaporation.

Figure 3. Physical Parameters of Vegetation

Figure 4. Hydrologic Cycle

e. Movement of water through openings in rocks.

f. Issue of water at the surface through springs, streams, and lakes.

Evaporation from the terrain and transpiration from the vegetation represents the transport of water from the earth back to the atmosphere, the reverse of precipitation. During the period when evapotranspiration exceeds precipitation, the moisture in the terrain profile decreases and results in a drier surface. During periods of excessive precipitation, the moisture index increases, either overcoming a moisture deficiency in the area or creating a surplus. The surplus may result in the formation of new water bodies, glaciers, and snowfields or in the enlargement of the older ones which could lead to flooding conditions (AFM 88-53, p. 90).

The drainage features of various parts of the world display a number of stream patterns. Variations in the pattern are the result of differences in the slope of the land upon which the drainage system developed and differences in the resistance of the underlying rocks to erosion (Figure 5).

The most common drainage pattern, known as dendritic, consists of a tree-like arrangement made up of a main stream and successively smaller tributaries joining it at acute angles; it occurs in regions where the water flows over materials that have relatively similar resistance to erosion. If the stream flows over a regular succession of elongated zones of weak and resistant rocks, such as is formed by folded or faulted structures, a trellis pattern develops. In this pattern, the major streams are arranged in relatively straight parallel lines with tributaries joining at right angles. Single mountain peaks and other places that have

Figure 5. Drainage Pattern Types

a centrally located high area with drainageways extending out from it in all directions have radial patterns. Irregular drainage systems are characteristic of regions that have been covered by continental glaciation.

3.1.5 CLIMATE AND WEATHER

Over a long period, some geographical elements influence the physical and chemical properties of terrain. These elements are: temperature (including radiation), moisture (including humidity, precipitation, and cloudiness), wind (including storms), pressure, evaporation, latitude, altitude, distribution of land and sea, and atmospheric phenomena.

Because these elements vary considerably throughout the world, there are many variations as well as similarities in climate throughout the earth.

Various systems have been formulated to classify climatic types. One noted system, based on the relationship between evaporation and precipitation, was devised in 1931 by C. W. Thornthwaite. He listed five major climatic groups - wet, humid, subhumid, semiarid, and arid - and assigned a rating for "precipitation effectiveness" to each group (Strahler, 1963, p. 327; Air Weather Service Manual 105-3; Curtis, 1966, p. 227).

In 1918, Wladimir Köppen developed a system of classifying the world's climate into 12 primary types according to annual monthly means of temperature and precipitation. His method, frequently modified, is generally accepted by terrain analysts as a suitable systematic and quantitative approach.

3.1.5.1 Major Types of Climate

The Köppen system divided the land areas of the world into 24 groups and utilizes the following 12 classifications to describe the world's climatic types. Figure 6 indicates the geographic locations of these climatic types.

(1) Tropical Rainy Climates (Af, Am)

Rainy tropical climates are characterized by high temperatures and heavy precipitation in all months of the year with no seasonal variation. Other terms used to describe this type are rainy tropics, humid tropical, tropical moist, and tropical rainforest.

(2) Tropical Wet and Dry Climate (Aw)

The type of climate that borders the rainy tropics on their poleward sides has high temperatures through the year and a rainy season followed by one that is distinctly dry. It is also designated by its principal vegetation type as tropical grassland or savanna.

Figure 6. Climates of the Earth (Köppen System)

(3) Semiarid Climates (BSh, BSk)

Broad transitional zones with semiarid climates separate the deserts from the humid climates. Since their one prominent feature is short grass vegetation, these areas are often termed "steppe" climates.

(4) Arid Climates (BWh, BWk)

Arid climates, including deserts, are those greatly lacking in moisture. Many of the arid climates (tropical, subtropical, and mid-latitude arid) have an annual precipitation less than evaporation.

(5) Dry Summer Subtropical Climates (Cs)

This type is characterized by a high percentage of sunshine in all seasons, and by dry, warm to hot summers and mild, rainy winters. Since such conditions are most widespread in the borderlands of the Mediterranean Sea, the climatic type is often termed as Mediterranean or Mediterranean subtropical.

(6) Humid Subtropical Climates (Ca)

Areas with this climatic type are on the eastern sides of continents in the lower middle latitudes and have hot summers, mild winters, and abundant precipitation in the warm season.

(7) Mid-latitude Marine Climates (Cb)

In many coastal regions of the middle latitudes, particularly west coasts, the climate is characterized by mild winters, cool summers, and relatively high precipitation. This type of climate is also designated west coast marine or temperate marine.

(8a) Humid Continental Climates, Warm Summer Phase (Da)

This climate has great differences between the long hot summer and cold winter temperatures, changeable weather in all seasons, and some precipitation.

(8b) Humid Continental Climates, Cool Summer Phase (Db)

The cool summer phase of this climate is similar to the warm summer phase as described in (8). The major differences are that the cool summer is shorter as the result of lower temperatures in the high latitudinal locations.

(9) Subarctic Climates (Dc, Dd)

This climatic type has long cold winters, short summer seasons, and great extremes of temperature. Other terms used to describe it are polar continental, boreal forest, or northern coniferous forest.

(10) Polar Marine Climates (ET)

The Arctic and Antarctic regions have a harsh environment with very low temperatures.

(11) Ice Cap (EF)

The two types of polar climates are polar marine and ice cap. They have similar harsh environments and weather characteristics, but vary often within and between the arctic and antarctic regions. The ice cap climate has severe cold temperatures, high winds, light precipitation, and a short summer-like season with a few days above freezing and sunshine.

(12) Highland

Differences in elevation and in exposure to winds and sunlight result in a great variety of climatic features in highland regions. Mountain climates cannot be easily classified on the basis of similar temperatures and pressures on a world scale. Climates of mountainous regions are frequently termed undifferentiated highland.

3.2 Methods of Analysis

3.2.1 DATA ACQUISITION METHODS

Three methods are used for acquiring terrain data: contact, non-contact, and indirect. These methods are described briefly below and fully in Appendix C (see Figure 7).

Figure 7. Data Acquisition Cycle

In the contact method, direct measurements of factor and factor class values are made on the ground. This method is the most reliable, since it yields usable quantitative data, but it is costly, time-consuming, and not always feasible.

In the non-contact method, remote-sensing instrumentation is used to obtain images of the terrain or recorded values of emissions from certain terrain properties (Figure 8). Although the non-contact method is easy to use and expedient, the accuracy and reliability of the resultant data are much less, generally, than are those of the contact method. The non-contact method is described in detail in Chapter III.

The indirect method of terrain data acquisition is employed when measured data are lacking and an area is inaccessible. Basically, the method entails employing intuitive scientific deduction to obtain an appropriate analogous analysis. Certain terrain characteristics can be predicted by comparing an unknown area to a known area that is similar in geology, topography, landforms, soils, climate, and vegetation. This method is frequently used in combination with the others to provide supplementary information to an analysis (Grabau, 1967b, p.18; Belcher, 1948).

3.2.1.1 Terrain Evaluation

The rationale of evaluation is largely the development of reasonable conclusions from an analysis and interpretation of measured and inferred data. The conclusions must relate the influence of terrain on a proposed activity whose performance can be predicted in any defined terrain complex (Figure 9).

Terrain studies for military application have the following specific goals:

- a. Terrain Classification, Quantitative (describe, classify, map, and establish analogs)
- b. Effects on Military Activities in Known Areas (available data and specialized experience)
- c. Factor/Effect Relationships (theoretical analysis)
- d. Field Testing of Theoretical Studies (validation of critical values)
- e. Sensors for Determination of Terrain Factor Values (remote sensing from airborne or orbital altitudes)
- f. Prediction of Quantitative Effects in Unknown Areas (elimination of pre-mission reconnaissance)
- g. Data Storage and Retrieval (accumulation of information for prediction)
- h. Selection of Flexible Alternative Conditions (varied response to meet changing tactical situations and environmental factors)

(1) Performance Prediction

The most efficient prediction concerning the success (that is, performance) of a proposed activity is achieved when all the requirements of a proposed activity and all terrain factor values are known prior to the evaluation. The principles

Figure 8. Synthesis of Data From Non-Contact and Contact Methods

Figure 9. Terrain Evaluation for Military Use

governing an objective, rapid, and accurate evaluation of terrain are: (a) the relationship between the terrain and the activity must be known in mathematical terms in the study and analysis phases; (b) a set of analytical models for each selected terrain factor relevant to the activity must be formulated; and (c) the evaluation must be based on the designated factors in the models and their critical values (Grabau, 1967b, p. 18).

(2) Evaluation and Prediction Procedure

The procedure for obtaining and disseminating evaluation and performance-prediction data is outlined below and shown diagrammatically in Figure 9. The terrain analyst should:

- a. Define and understand the military need and delineate specific activities in mathematical terms.
- b. Isolate the relevant terrain factors and their subclasses and construct a mathematical model of each subclass.
- c. Determine the critical terrain factor class value for each model.
- d. Obtain and analyze all relevant terrain factor data near the site of the proposed activity.
- e. Determine the gaps in the required data, and plan to obtain that data.
- f. Analyze all the information and make preliminary conclusions.
- g. Consult with knowledgeable professionals and/or technicians on any hazy aspect of the total problem.
- h. Review the analysis of source information, evaluate for specific effects on the activity, and make final conclusions and recommendations. Consider vulnerability of terrain to possible enemy action.
- i. Prepare a report covering all major aspects of the problem, and include in it large and medium scale maps, annotated ground and aerial vertical and stereoscopic photos, charts, diagrams, graphs, engineering data, and important references. Radar, infrared, other film (color, camouflage detection), and other imagery would be included.
- j. In cases of major problems, document all important information in detail. The conclusions and recommendations should be brief, clear, complete, and supported by data or information contained in the body of the report. Useful photographic documentation, and other imagery properly annotated, should be included as appendix material.
- k. The team concept of analyzing a problem or activity should be the standard procedure. A special group of three to six professionals or technicians should be assigned the problem, with a target date for completion. The professionals should be from such fields as civil engineering, geology, geography, soil science, botany, ecology, forestry, and photogrammetry.

1. The terrain analyst will emphasize the foregoing steps related to his particular objectives, using the basic concepts of his scientific field, the criteria which they provide, and applying the method of reasoning appropriate to the problem. In the absence of specific data, the interpretation is based on reasoning by analogy. For this step, comparison of the unknown terrain complex with its nearest analogous terrain of known characteristics is the primary point of departure in the analysis.

The possibilities suggested by such comparisons are subjected to independent checks before any final judgment is rendered. Critical examination is made to appraise the correctness of the analogy, to consider possible ambiguities, to explore alternate explanations, and to ascertain the extent to which explanations conform with basic principles and data of the scientific disciplines. Analysis and synthesis of the data compared with the analogous conditions can contribute to a reliable evaluation.

(3) Special Procedures for Site Selection

As a supplemental guidance to the approach outlined in (2), the following steps will provide the required data for effective integration, reduction, and evaluation in response to the varying siting problems.

a. Determine data on: regional and local topography, geology, hydrology, soils, vegetation, climate and weather, and accessibility (roads, railroads, air, water, and ports).

Terrain data of engineering significance includes:

- 1) Regional relief within a 25-mile radius of the potential site with about 20-ft accuracy, local relief within a 5-mile radius with about a 10-ft accuracy, and site area within a 3-mile radius with about 1-ft accuracy
- 2) Soil profile down to 10 ft or bedrock
- 3) Surface and ground water characteristics
- 4) Geological conditions
- 5) Vegetation location and type, root systems, and density
- 6) Meteorological factors
- 7) Accessibility and logistics requirements
- 8) Perimeter defense advantages.

b. Prepare and compile all the data in item a., above, in large, intermediate, and small scale maps appropriate to the type of use and annotate the aerial and ground photography details.

c. Conduct a survey of the site to determine availability of local indigenous construction materials, water supplies (potable and construction), and topographic controls.

- d. Prepare engineering plan of site layout and development.
- e. Compute grading and excavation requirements, estimate effort required to remove obstacles, and plan for protection against serious natural hazards.
- f. Perform final evaluation of all the environmental factors influencing the site utilization.
- g. Compute the total construction effort and resources in terms of personnel, equipment, materials, and time needed to ready the site for use.
- h. Prepare final report in a folio form on the site including recommendations, alternate sites, advice in site preparation, accompanied by properly annotated overlap maps, ground and aerial photographs, and other essential background information.
- i. Check with user to record for future guidance the comparison of predicted site conditions and recommended effort with the final site selection, development, and expended construction effort.

Selection of sites for installations, tactical positions or mobility of weapons and troops, and aircraft and vehicle trafficability generally follow a similar plan of investigation.

3.2.2 CAPABILITIES AND LIMITATIONS OF TERRAIN ANALYSIS

Experience has demonstrated that significant savings of time and effort in terrain interpretation are obtained by a combination of contact and remote-sensing methods. The viewing of terrain in three-dimension, thus presenting it in realistic perspective, is invaluable for improved planning. The non-contact and indirect methods have limitations which degrade an optimum analysis of terrain in completely quantitative terms.

3.2.2.1 Masked Terrain Conditions

One of the major limitations to an accurate evaluation of terrain is that surface materials can mask the diagnostic characteristics of underlying formations. Vegetation, glacial remnants, and wind-blown or water-transported materials are common types of masking deposits. In addition, relic and pseudomorphic landforms produced from different materials, conditions, and geologic processes are unfamiliar varieties and can confuse the interpreter. Current knowledge regarding the origin, distribution, and relationships of many known types of landforms is inadequate, and additional varieties remain to be discovered and studied. Although external characteristics may be diagnostic of internal conditions and underground materials, the interpreter is handicapped unless the surface details of the terrain are evident and simulate the classic examples of landforms.

3.2.2.2 Available Information

Terrain data obtained for other objectives (economic or agricultural purposes, etc.) is available, but it is generally not directly applicable to specific military needs. Photointerpretation used in conjunction with this data could provide some of the necessary details.

3.2.2.3 Quality and Accuracy of Source Materials

The reliability of interpretation is proportional to the availability of large-scale, recent, and accurate maps and photographs (aerial and ground). Ideally, the map and photo scales for microterrain studies should be from 1:2,000 to 1:10,000; for general terrain analysis they should be from 1:15,000 to 1:40,000. Many interpretation difficulties arise from the need to use expedient procedures and maps and photos of unsuitable scale and poor quality. Factors of cost, time, priority, or specific requirements often outweigh the interpreter's preference and limit the reliability of his interpretations.

3.2.2.4 Training and Field Experience of the Interpreter

The level of skill, formal training, and field experience of an interpreter directly affects the quality of his analysis. Many of the subtle phases of interpretation - denoting interpretative skill and confidence - are not developed until a number of successful predictions have been achieved in unknown areas. The common weakness is lack of training in a pertinent scientific discipline.

3.2.2.5 Inadequate Methodology

To overcome existing limitations in the field of terrain analysis, a source of ready and reliable data must be made available to the interpreter. This goal could be achieved by the establishment of a data bank, by continued effort to supply and store new data, and by incorporation of the following types of information:

(1) A Global Atlas of Regional Landforms - Aerial Views

Representative examples of landform types and their variations in all types of geologic, geographic, and climatic environments should be depicted in an atlas. Comparisons of different geographic areas with analogies in accessible areas such as in the United States would be included.

(2) Types of Terrain Features

The characteristics of the terrain from microfeatures to vegetation, soil conditions, bedrock, surface and subsurface drainage, and other related factors such as engineering properties within the global environment should be summarized and illustrated in detail. Such summaries would compare stereographic data of familiar areas with that from unknown areas.

(3) Case Histories of Terrain Studies

Detailed reports on locations that were checked on the ground and the results compared with data obtained through remote sensing would be of great value as background, training, and reference material. Such reports would describe the predictions made, criteria used, source data, and the extent to which predictions were confirmed by ground testing. The reasons for inaccuracies in the interpretation would also be covered. A folio of all site maps, charts, graphs, aerial and ground photographs, and other imagery, plus supporting bibliographic references, would be a part of the documentation.

(4) Increased Use of Illustrations & Annotated Imagery

All reports issued on the investigation of terrain should contain annotated photographic and other imagery showing terrain characteristics. This would contribute to an increase of background information for further reference and analysis.

(5) Further Research

Fundamental research through controlled experiments should be continued on the origin, nature, and distribution of landforms and microfeatures and their properties in different environments. Bare, natural, and cultivated vegetated surfaces should be investigated for clues to specific terrain conditions that can be recognized on aerial imagery (Williams, 1964, p. 98; Neal, 1965, p. 150; Needleman, 1962, p. 70).

As new types and varieties of terrain are studied, variations must be inventoried, scientific complexities must be unravelled, ambiguities resolved, and controlling factors evaluated. This new information could facilitate improved terrain interpretation (Committee on Geophysics and Geography, 1953, p. 26).

4. CRITERIA

Since the critical values of terrain parameters change with each new military application (size of tanks, etc.), a thorough knowledge of the geology of the ground feature and the surrounding terrain is necessary in order to determine the engineering properties. The critical values are based on the quantitative effect that the application will have on the individual natural features.

The criteria established from performance tests, etc., determine such applications as trafficability of aircraft, vehicles, and troops; concealment and cover; availability of water and construction materials; and types of construction problems.

5. VALIDATION

The quality of the terrain evaluation is directly proportional to the usability of the investigated terrain according to performance predictions. Reliability is increased if the predictions are supplemented with adequate measured data. The best approach is to use the data in a check and balance method to eliminate possible limitations in the proposed use of the terrain for each application. Field, laboratory, and sub-surface investigations can either confirm or deny such use. Comparison of unfamiliar terrains with their nearest analogues of known characteristics and performance predictability is the standard practice in lieu of sufficient ground data (Burns, 1960, p. 25; Needleman and Pressman, 1962, p. 190).

III. Remote Sensing

C. E. Molineux

I. INTRODUCTION

In terrain analysis, aerial photography is the most widely used type of remote sensing, and most of the photos obtained are black-and-white, taken on panchromatic film at scales ranging from 1:10,000 to 1:50,000. Such photos, used in conjunction with on-the-ground observations, usually provide the best means of obtaining a ground inventory. To be of maximum usefulness, the aerial photography must have been taken with proper consideration given to film, filter, resolution, time of day, and season of the year. Each land structural element has a critical scale that is optimum for interpretation, and the photo patterns pertaining to the distribution of tones and textures of an image are critically important.

Electromagnetic sensing outside the visible spectrum is not extensively used at this time, but research and development are in process, especially in the imaging infrared and radar regions. As experience is accumulated, such imaging or non-imaging sensors will come into greater use and acceptance.

Non-imaging sensors usually record a phase of electromagnetic radiation emitted or reflected from a surface. The phase may be an absolute quantity in various spectral regions, such as radiometric temperature, or time-distance relations of received radiation, as in microwave or radio-frequency-reflection devices. The relationship may be phase or polarization, absolute reflectivity

values, or similar factors associated with sub-surface conditions determined by the radio-frequency penetration capability of such devices. Gamma-ray sensing, radio-frequency sounding, and swept-frequency radar techniques are examples of this capability.

Some limitations are due to the relationships of the terrain electromagnetic emissivity and the sensor's capability to detect or record the same.

In general it may be said that aerial photography enables estimation and limited measurement of the physical and engineering properties of surficial terrain. Infrared sensing in the 3 to 5 μ wavelength region of the spectrum best indicates cultural or artificial thermal energy sources. Infrared in the 8 to 14 μ region coincides with the broad envelope of natural earth radiation, and enables sensing of surface or near-sub-surface soil conditions that are important for mobility purposes.

Microwave radiometry has much promise for terrain material identification and discrimination and for mapping of sub-surface conditions. Radar techniques have great potential for distinguishing surface materials, determining moisture content and vegetation conditions, and for recording engineering geologic patterns such as outcrops, faults, and stratification. Airborne magnetometry is useful in mapping near-surface igneous material.

To expedite the acquisition of reconnaissance, engineering, and geologic data, remote sensing methods are used. Basically, the method entails acquiring information about an object or phenomena by using an information-gathering device that does not have to come in contact with the object under investigation. The data obtained by remote-sensing devices can be utilized to further our knowledge relevant to the earth and its environment, to solve engineering problems and problems relevant to the exploitation or conservation of natural resources, and to promote national defense. The USAF Scientific Advisory Board (AFSAB) has recently endorsed the need for continuing such application of remote sensing techniques (USAF Scientific Advisory Board, 1966).

Present electromagnetic sensing technology and the ability to operate from platforms above the earth has permitted the development of systems having a greatly increased ability to sense the meaningful characteristics of the earth and its environment. Increased information can be obtained through the use of combinations of sensors, with each individual sensor exploiting a different portion of the electromagnetic spectrum. Infrared, radar, passive microwave, geochemical, spectrophotographic, and spectroradiometric sensor techniques show much promise in providing surface and subsurface information. Much of this information is also needed in target-background, signature-characterization efforts.

With remote sensing devices it is possible to map large areas, obtain information about the physical characteristics of objects or phenomena, and monitor conditions that change with time. Regardless of the application, especially when used in aircraft or spacecraft vehicles, these devices provide a means of acquiring data on environments otherwise inaccessible because of physical limitations or political restraint. In some instances, remote sensors may be the only means of acquiring a certain type of data; in others, they may be the more economical means. The vast potential of satellite sensing has been documented for NASA by the University of Michigan (University of Michigan, 1966a). In addition, non-imaging sensors (including air-droppable devices) can be used to obtain specialized data. Ground-based surveys, when feasible or allowed, may use additional sensors that require contact with the surface to obtain unique data. In the airborne mode, information obtained photographically in the visible portion of the spectrum can be supplemented by data recorded by other sensors used in a multi-disciplinary approach.

Various charts and effectiveness diagrams tabulating the terrain and environment parameters detectable and measurable by pertinent remote sensing techniques have been prepared by organizations conducting such activities. One such comprehensive chart prepared by the U. S. Army Engineer Waterways Experiment Station (USAEWES) is shown as Figure 10. Others are plentiful in the literature. The electromagnetic spectrum, sub-divided to show the generally accepted sensing regions, is drawn in terms of frequency and wavelength in Figure 11.

Countless governmental, industrial, and university organizations are conducting research and development, testing, and determining the applications of remote sensors. Indicative of the general interest and emphasis in this scientific field is a long-term comprehensive study by the University of Michigan, supported by many federal agencies, which has featured periodic Symposia to provide an information exchange medium on the state-of-the-art and applications of all unclassified phases of remote sensing (University of Michigan, 1962, 1963, 1965, 1966b). NASA has published extensively on the use of remote sensing in its earth resource program (Badgley et al, 1967), and an International Symposium on Electromagnetic Sensing of the Earth from Satellites was held in late 1965, sponsored by American Geophysical Union, American Meteorological Society, and the Optical Society of America (Zirkind, 1967). The Michigan Symposium proceedings and the Journal "Photogrammetric Engineering" of the American Society of Photogrammetry (ASP) are highly recommended for presentations of current status and applications.

Figure 10. Remote Methods for Characterizing Environmental Factors

Figure 11. The Electromagnetic Spectrum and Frequency Wavelength Conversion Nomogram

2. AERIAL PHOTOGRAPHY

The principles and uses of aerial photography using conventional black-and-white film are well known and will not be re-stated here. Such photography with panchromatic film uses the complete visible spectrum, except that haze, or minus-blue, filters are occasionally introduced. It provides a high resolution and generally distortion-free visual map of the terrain essentially as the human eye perceives it. In this type of photography most images have the objects of interest recorded in varying shades of gray on the photographic emulsion. The problem of photo-interpretation begins here. In many situations the image is of a familiar object or terrain feature, and its geometric properties (size, shape, shadow, or texture) plus its location, contrast, and relationship to surrounding objects enable ready identification. However, when the object is unfamiliar or exhibits a different or unaccustomed tonal value on the image, the interpreter's judgment and experience becomes critical (American Society of Photogrammetry, 1960, p. 99).

2.1 Resolving Power

For a given film format (W), the smallest detectable elevation feature is dependent on the flight altitude (H) and the resolving power of the camera system (R). This is expressed as $\frac{\Delta H}{H} = \frac{1}{274WR}$ where ΔH , H, and W are in feet and R is the commonly used term of lines per millimeter. This capability is shown for various $\frac{\Delta H}{H}$ combinations using a 9-inch film format in Figure 12. The range of resolution hachured (up to 80 lines per millimeter) represents that presently in the unclassified state-of-the-art of aerial photography (Itek, 1962, p. 50).

Figure 12. Resolving Power of Photography Varying With Flight Altitude

2.1.1 GROUND RESOLUTION

Photographic interpretation for detail from aerial photography ranges from scales of 1:2,000 to 1:10,000, with ground resolution of object size obtained in terms of inches. In contrast, the common scales for photointerpretation for reconnaissance purposes range from 1:10,000 to 1:40,000, with ground resolution attainable in terms of feet. The common photographic mapping scale is 1:60,000, depending on the use of adequate ground-control points (American Society of Photogrammetry, 1960, p. 773).

The use of aerial color photography greatly extends the criteria that can be used for terrain property identification. Although the human eye-brain combination can only discriminate about 128 shades of gray, it can discriminate several million different colors.

There are many problems associated with the use of aerial color photography, apart from the cost of this film and the necessary processing techniques. The glass covering the camera wells in photographic reconnaissance aircraft are rarely of high optical quality and may act as an image-degrading filter with color tones appearing on the emulsion being different from the natural object colors. The optical properties and color correction of the camera lenses themselves, the quality, amount, and atmospheric absorption of the reflected solar radiation, and the variability of the dyes making up the film emulsion itself are other factors that can contribute to image color variability. The American Society of Photogrammetry has published a "Manual of Color Aerial Photography" that is highly recommended for pertinent information. A voluminous report entitled "Photographic Instrumentation - Science and Engineering" prepared for the Naval Air Systems Command (Hyzer, 1965) gives a thorough coverage of all photographic equipment and applications. The Navy Oceanographic Office (Vary, 1967) has recently conducted a test of the water-penetrating ability of color photography, in flights from 2000 to 30,000 ft altitude. It was found that 100-ft-sq offshore targets could successfully be detected at depths of 65 ft, even in rough water at sun angles from 20° to 40° .

Color photography from satellite altitudes provides coverage of earth areas of unprecedented scope and contrast. An example of this capability is the preparation of tectonic maps of the Middle East at one to one million scale by the North American Aviation Science Center under NASA support (Abdel - Gawad, 1967). These maps, prepared entirely from GEMINI photographs, show faults, shear zones, and geologic structures, often extending for hundreds of miles, that are unrecognizable in lower-scale photography.

Aerial panoramic cameras have been developed and used for over a decade to combine wide-area photographic coverage with very high resolution. They generally have a curved film plane and a high-quality, narrow-angle lens that scans across the flight path of the aircraft so as to "paint" an image of a wide

swath of ground onto the film. The maximum scan angle is 60° either side of the vertical. With a focal length of 12 in., very high altitude photography can be obtained without sacrificing image detail. Since the center of the lens rotates with the scanning arm, the sharpest possible image is always recorded on the film, even at the edges of the format. An example of the scope and high resolution of panoramic aerial photography is shown in Figure 13.

Modifications to aerial color film to eliminate the blue-sensitive layer have recently been proposed to film manufacturers. The standard yellow haze filter, would, therefore, not be needed, and a one-stop increase in exposure would be possible.

2.2 Multispectral Photography

Multispectral, multiband, and spectro-zonal photography are terms applied to the images simultaneously obtained through various filter combinations in narrow-band regions of the visible and near-infrared spectrum. The operating

Figure 13. Aerial Panoramic View of Terrain

principle of this technique is that different types or conditions of terrain reflect solar radiation differently throughout the photographic spectrum. By interpretation of the relative brightness or tonal contrast appearing on matched, narrow-band images, changes in soil or vegetation properties and composition or seasonal effects on the terrain can be detected and analyzed. Such information can be obtained in a more quantitative manner from this type of aerial photography than from conventional black-and-white or even color photography.

A nine-lens camera system (Figure 14), originally developed for ARPA nuclear test detection program (Molineux, 1965), has been used extensively by AFCRL and NASA for airborne terrain research programs. This "multiband" camera employs three rolls of film, each traversing three matched lenses equipped with appropriate filters to give a narrow-band input to the film. The part of the spectrum covered is from 400 to 900 m μ , with resolution of approximately 75 lines per millimeter. The resulting nine photographs, taken at one shutter click, are matched within 0.001 in. Six of the images are on two rolls of 70 mm aerial panchromatic film, and the other three are on one roll of 70 mm aerial infrared film. The lenses used are f/2.4, 150 mm with standard gelatin filters that give bandwidths of about 100 M μ .

Figure 14. Multiband Camera System

Extension of the camera's capability to gather signatures of terrain properties is provided by the use of horizontally and vertically polarized filters in two of the bands, and an ultraviolet transmitting lens in another band, applied when desired. The camera has image motion compensation, and can be flown at altitudes of from 600 ft to over 25,000 ft. A stabilized mount is desirable to provide vertical control of photographic coverage. A wide range of shutter speeds and apertures are available for use over varying conditions of terrain illumination.

AFCRL's use of the multispectral camera has covered terrain areas ranging from arctic glaciers through lava flows and coastal beaches to desert playas and tropical rain forests, all of interest because of their characteristic reflectance

properties. Analysis involves examination of the nine images from each exposure on a light table modified to display the three rolls of film together. Terrain anomalies or patterns of interest can be identified in terms of their reflectance changes for correlation with known patterns and conditions; selected frames can be used for color enhancement or superposition techniques, if desired. In special cases where very subtle tonal differences are worthy of more analysis, a micro-densitometer can be used to scan the original negative and yield the detailed reflectance values that were registered as gray tones.

The nine bands were originally chosen to provide wide coverage throughout the spectrum. Since some of these may give no additional or otherwise redundant reflectance information, a lesser number of bands may be practical. Other government agencies (Rome Air Development Center, Army Terrestrial Science Center, and National Aeronautics and Space Administration) and many commercial aerial photographic organizations have developed four-band cameras by clustering four separate 70-mm cameras and synchronizing their shutters, which enable worthwhile multispectral photography.

An example of the imagery generated by the nine-lens systems of AFCRL, and the interpretation of the tonal changes evident in contrasting wavelength regions, is shown in Figure 15.

Figure 15. Multiband Photography

2.3 Color-Distortion Photography

"Camouflage Detection" (CD) or Ektachrome Infrared (IR) film is a high-resolution, false-color film that differs from normal color film by having its three sensitized emulsion layers record green, red, and infrared radiation instead of the usual blue, green, and red. It has high color contrast, brilliance, and haze penetration capability. The colors, although appearing false to one's experience, provide a contrast enabling adjacent objects or materials to stand out distinctly. Although the high-resolution values cited by the manufacturer are not generally realized through exposure and processing, the clarity of CD images provides greater detail than comparable color or IR images. Figure 16 illustrates the visible spectral and sensitivity ranges of pertinent films.

The use of color-distortion photography also enables distinction between types and health of vegetation cover. Deciduous green foliage reflects green and infrared radiation, and film processing leaves magenta as the indicator for such vegetation; coniferous foliage is recorded as a darker magenta. Due to changes in IR reflectivity of foliage pigments, dead or diseased leaves are recorded in shades of light magenta to orange. The effectiveness of using CD film for determining vegetation cover properties has been pioneered and established by Dr. Robert Colwell at the University of California (Colwell, 1966).

Figure 16. Electromagnetic Spectral Sensitivity Ranges of Films

In addition, the use of color emulsions, particularly CD film, enables very good photographic penetration of water. Underwater terrain contours and obstacles can be recognized and mapped by this CD photography, enabling offshore beach or shallow-water charting for amphibious operations.

Objects in shadow or shade usually are not detectable on normal black-and-white images, but they stand out readily on CD film. Objects of different colors, which usually show the same shades of gray in black-and-white photography, have definite color contrasts when imaged on CD film. This is especially valuable during conditions of low sun angle or in oblique photography where long shadows are produced.

CD photography is best reproduced and evaluated as transparencies, since the full-color values cannot be duplicated on paper prints.

2.1 Polarized Light Photography

In real target-background situations, illumination is by both direct sunlight and diffused skylight. Light reflected from surfaces, in turn, is both coherent and incoherent. Light reflected from most surfaces is considered partially coherent, in that a rough textured reflecting surface is a fairly good diffuser since the surface as a whole reflects diffusely while the many small facets of which it is composed reflect specularly. The expression $\frac{c}{\lambda}$, where c is the rms surface roughness and λ is the wavelength of the incident light, can be stated as a measure of the light-diffusing property of the surface. Multi-reflected light, in the case of a many-faceted rough surface, is randomly polarized. The intensity ratio of multi-reflected to directly reflected light is dependent on the distribution of facet orientation. This ratio generally increases with increasing total reflectance. Hence the degree of linear polarization of light reflected from diffusing surfaces is inversely related to the total reflectance.

The Naval Weapons Center, China Lake, California, has conducted many polarized photography experiments on natural terrain and man-made surfaces. Their experiments verify this relationship and prove that polarization contrasts can be used to detect and discriminate background and target materials, in both direct and diffuse illuminations. Several of their reports present a wide variety of natural materials photographed in both the visible and near-infrared spectrum. It was found that the largest polarization contrast exists in the 500 to 700 and the 800 to 1000 m μ region of the spectrum.

In general it can be stated that polarization contrast, like chromatic and luminous contrast, can be observed for any material, and that a discrimination capability is therefore present in the degree of polarization of light reflected from objects in any scene. Airborne measurements were carried out at NWC using a variety of polarizing filters in aerial cameras, and a polarizing TV camera was used in ground-based experiments.

2.5 Infrared Photography

The use of black-and-white infrared film in aerial cameras has both advantages and disadvantages. This film is designed to be sensitive in the red and near-infrared wavelength region, but it is also sensitive in the ultraviolet region below 530 $m\mu$. So that only the red and infrared portions will be recorded, a Kodak 89B filter is used to eliminate the ultraviolet and almost all the visible portion of the spectrum below 700 $m\mu$.

The difference in black-and-white IR photography as compared to panchromatic is most evident in the recording of water and foliage, as reported from Navy studies (Naval Reconnaissance and Tech. Support Center, 1966). Since water does not reflect or transmit infrared radiation, and the blue portion of the rest of the spectrum reflected from water surfaces is filtered out, water appears very dark or black with respect to land which is a lighter gray tone. Grass, bare earth, and water might all show an equal density or gray tone on panchromatic film. However, IR film will show the grass as light gray and earth as medium gray, enabling ready distinction. Delineation of shoreline contours is an immediately obvious capability.

IR films record healthy, lush vegetation in the lightest tones, while vegetation that does not have enough water reflects less infrared energy and shows as medium tones, due to changes in the relative amount of chlorophyll and pigments.

The filtered infrared sensitivity of this film also makes it useful for haze penetration, since the less-scattered rays are recorded. This infrared sensitivity also provides increased tonal contrast between man-made and natural objects, such as an asphalt runway against an adjacent grass or soil background.

The resolution of black-and-white IR film is noticeably poorer than panchromatic. Most lenses for aerial cameras are designed for visible light and therefore focus the infrared rays behind the normal focal plane, as shown in Figure 17.

Figure 17. Focus of Infrared Wavelengths With Focal Distance

Refocusing or lengthening of the focal distance is therefore required with IR film. Not all of the IR wavelengths will be brought into the film plane, but a sufficient portion of them will fall into focus to produce an acceptable image. The 89B filter provides a bandpass of 200 m μ to minimize the possibility of degraded images generated by the lens-film combination.

A photometer or exposure meter cannot give reliable values to determine proper IR film exposure, since wavelengths beyond the visible spectrum do not register on these devices. The usual technique is to use the manufacturer's exposure index as modified by the appropriate filter factor. Areas highly reflective in the infrared, such as vegetation, require less exposure than industrial areas. Examples of comparison of simultaneous panchromatic and IR photography are shown in Figure 18.

3. INFRARED SCANNERS

In the last decade, an airborne, electromechanical, imaging, infrared radiometer, generally called an IR scanner, has been widely used for reconnaissance. They are now proving valuable for gathering geophysical data inasmuch as they generate a two-dimensional thermal map indicative of surface or sub-surface parameters.

The earth radiates energy in a spectrum approximating that of a blackbody at 300°K , with a maximum near $9.5\ \mu$ wavelength. It also reflects solar energy whose spectrum approximates a blackbody at 6000°K with a maximum near $0.5\ \mu$. The energy emitted by or reflected from the earth's surface is selectively absorbed by the atmosphere, with only the part that passes through "atmospheric windows" reaching an airborne detector, as shown in Figure 19.

In a scanner these detectors, generally sensitive to radiation between 3 and $5\ \mu$ or between 8 and $14\ \mu$, as shown in Figure 20, convert the radiation into wide-band electrical signals that modulate a light source or cathode ray tube. Recording is generally made on film passing in front of the tube at a rate proportional to the velocity height ratio of the aircraft. Lateral coverage is provided by rotation of a collecting mirror, and forward coverage by the motion of the aircraft. The resulting image gray scale is thus a function of the detected earth surface temperature. Tape recording of scanner output enables preserving a higher dynamic range of imagery for enhanced evaluation.

Figure 19. Infrared Transmission Through the Atmospheric Windows

Figure 20. Infrared Detector Sensitivity Variation With Wavelength

Development of infrared scanners was pioneered by the University of Michigan, Texas Instruments, Inc., and HRB-Singer, Inc. Many terrain surveys using infrared scanning are being conducted by AFCRL, USGS, NASA, ONR, and ATSC (CRREL). Examples of such programs are thermal mapping of soil properties, vegetation, fresh- and salt-water ice patterns, volcanic activity, forest fire distribution, crevasses in ice, and recent applications to archaeology. The obvious military reconnaissance and detection programs using this technique are beyond the scope of this report.

Typical infrared scanner imagery obtained by AFCRL for terrain evaluation purposes is shown in Figure 21.

1. ULTRAVIOLET SENSING TECHNIQUES

A generally held opinion is that the absorption of solar radiation by the ozone in the earth's atmosphere causes a nearly complete attenuation of ultraviolet energy. However, experiments have proved that sufficient ultraviolet light may be available for daylight photography using sensitive film and appropriate filters. Also, it has been proved that many terrestrial materials have selective responses to narrow-band ultraviolet illumination.

Figure 21. Typical Infrared Scan Imagery

AFCRL, AFAL, USGS, ATSC, and the Army Tank Automotive Center are government agencies that have performed experimental photography using ultraviolet transmitting filters to distinguish targets and terrain backgrounds. Texas Instruments, Inc., has done similar studies for material discrimination. AFCRL is incorporating an ultraviolet-transmitting lens in its aerial multispectral camera for airborne terrain surveys.

A promising application is being conducted by USGS (Hemphill and Vickers, 1966a) involving use of an ultraviolet video imaging system for detection of luminescent minerals and rocks and for possible discrimination among non-luminescing materials on the basis of selective absorption of energy between 330 and 410 m μ wavelengths. Their scanning system employs an S-11 photomultiplier detector and is filtered to accept only wavelengths shorter than 410 m μ .

Airborne scanning imagery in the ultraviolet has been collected by USGS from up to 15,000-ft altitudes over representative test sites (Hemphill, 1966b) and it shows distinct contrasts between materials and vegetation. Sandstone and carbonate materials with a minimum amount of moisture are particularly reflective in the ultraviolet.

5. PHOTOMETRY AND SPECTROMETRY

Data on the visible and near-infrared spectral reflectance of various elements of the earth's surface are of the utmost value in photointerpretation. These data can permit discrimination of materials by their tonal brightness appearance on aerial photographs. In addition, spectral reflectance measurements from field or airborne sensors, extending into the far infrared in some instances, allow determination of the mineralogy, chemistry, particle size, and surface roughness of materials.

Reflectance measurements are made by a variety of photometers, spectrometers, spectrophotometers, and radiometers, usually filtered for narrow-band outputs.

One of the earliest and still most comprehensive experimental studies of reflectance was published by Krinov in 1953. The National Bureau of Standards long-time work by Keegan and his associates on vegetation reflectance (Keegan et al, 1956; Gates et al, 1965) have been major references in the United States. Since then many organizations (MERDC, ATAC, AFCRL, NWC, and NASA) have conducted extensive measurements of rocks, soil, vegetation, and man-made substances. A chart compiled by the University of Michigan is given in Table 1. The compilation by Steiner and Gutermann (1966) is a valuable survey of Russian data since the original Krinov studies.

Under NASA Support, R. J. P. Lyon of Stanford (Lyon and Patterson, 1966) pioneered the gathering and interpretation of geological reflectance signatures in the 8 to 13 μ infrared region. By matching the measured signatures with pre-determined ones in the memory of a computer, rock composition can easily be identified in field operations. Real-time determination at rates up to seven signatures per second, utilizing a filter wheel, are feasible, permitting sensing from aircraft. A typical group of emissivity signatures gathered by Lyon are shown in Figure 22.

6. RADAR SENSING TECHNIQUES

High-resolution, side-looking radar in the present state-of-the-art can be extremely useful for airborne determination of local geologic features, particularly geomorphic and gross relief patterns. A beam of radar energy provides unidirectional illumination rather than the multidirectional illumination given by atmospherically diffused sunlight. It therefore produces imagery that is composed of a great number of specular reflections, as the relationship of the surfaces to each other has a strong influence on the intensity of the returned energy recorded on the film. Small variations in surface relief thus imaged may express geologic phenomena such as folding, faulting, and drainage channels. Similarly, surface reflective characteristics based on the relationship of surface roughness to the radar wavelength can reveal to the interpreter the probable physical characteristics of the material. Fine materials such as clay, silt, or sand are imaged as a "no return", while coarser material such as rocks, a talus slope, or a lava flow show strongly textured patterns. Examples of such radar images are given in Figure 23, with interpretative captions, as reported by Autometrics Corp. (Bienvenu and Pascucci, 1962; Moore, 1966).

Table 1. Reflectance of Terrain Conditions

Type	Reflectance %	Peak Wavelength λ (μ)
Water Surfaces		
Inland Waters	3-10	0.4810
Oceans	3-7	0.4810
Bare Areas and Soils		
Snow	70-86	0.4810
Ice	75	0.5795
Limestone	63	0.5790
Calcareous Rocks	30	0.5790
Granite	12	
Mountain Tops (Bare)	24	0.5816
Sand	18-31	0.5616
Clay Soil	1.5-15	0.5828
Ground Bare (Rich Soil)	7.5-20	0.5832
Field (Plowed)	20-25	
Vegetative Formations		
Coniferous Forest	3-10	0.5744-0.5758
Deciduous Forest	10-15	0.5719-0.5858
Meadow (Dry Grass)	3-8	0.5758
Grass (Lush)	15-25	0.5719
Field Crops	7-15	0.5858
Man Made		
Buildings (Cities)	9	0.5828
Concrete	15-35	

Although the resolution and definition of side-looking radar images are much poorer than aerial photography, radar has many operational advantages over the latter. Returns can be obtained through any weather conditions except heavy rain; the day- and night-scanned images are equally good; returns can be obtained from high altitude and at high speeds; coverage extends many miles to either side of the aircraft; and the scale is built into the system.

There are two types of imaging radar, the noncoherent or real aperture type of system that uses a large antenna, and the coherent or synthetic aperture type employing a relatively small antenna along with an elegant signal processor. Both are generally used in a direct side-looking aspect. With noncoherent radar,

Figure 22. Spectral Emissivity of Common Rocks
(Lyon and Patterson, 1966)

Figure 23.
Radar Imagery

resolution is determined by the antenna beamwidth; with coherent radar, resolution is achieved by the processor's ability to separate targets closely spaced in azimuth by virtue of their time-displaced doppler histories.

Synthetic aperture imaging systems function as follows: The aircraft carries a small side-looking antenna producing a fairly broad beam that scans the terrain by virtue of aircraft motion. The terrain is illuminated at an appropriate sampling frequency by either a narrow pulse or a pulse-compression waveform, depending on the resolution and range requirements. The reflected signal, after intermodulation with the coherent transmitter reference, is stored. Successive terrain-signal samples are then processed in a manner analogous to the coherent weighted summation carried out by a large antenna array. The actual signal processing is usually carried out by optical methods involving film as the storage medium; however, real-time systems have been built using a storage tube as the memory and electronic circuitry for the matched-filter processing. The resolution of a synthetic aperture radar, in contrast to most sensors and optical devices, is independent of range as long as an adequate signal-to-noise ratio exists.

Radar imaging provides location as well as magnitude of the back-scattered return. Because imaging systems operate over a rather restricted portion of the RF spectrum and towards the higher end (typically X and K bands), more is determined about the geometry of a radar target as opposed to its properties as a radar reflector.

Most modern side-looking radar systems are classified as to their specifications and operating parameters, and their use for reconnaissance and target detection purposes is well known and beyond the scope of this report.

A non-imaging four-band radar system has been used by the Army Engineer Waterways Experiment Station for several years in investigations of the radar power return as functions of soil properties. The system comprised K-, X-, C-, and P-band frequencies beamed on soil samples from a 50-ft elevation at various incident angles, as shown in Figure 24. Test conclusions were that such radar

Figure 24. Army WES Experimental Radar System

sensors can provide information on surface water and moisture content of deep homogeneous soil samples. In addition, a swept-frequency radar system can locate ground or surface water. Research investigations are now being conducted for boom-mounted instruments carried on ground vehicles transversing natural terrain.

Stereoscopic or three-D radar is still in the research stage, and several commercial electronic organizations are in the process of developing feasible systems.

Such newer developments have not downgraded the use of high-definition radar-scope photography for studying the earth's surface. Detailed analysis of such imagery has been reported by Texas Instruments (Feder, 1960) and by Acadia University (Cameron, 1965); their analysis shows marked delineation of fracture patterns, folds, and faulting, and distinct erosional patterns.

Optical radar, laser radar, opdar, and lidar are terms applied to the use of narrow-band or coherent light propagation and return similar to conventional radar. Many organizations are conducting research on these techniques, but to date they are used mainly for detection and ranging purposes. Identification and measurement of earth properties and characteristics by such coherent-light beam is still an application awaiting further study.

6.1 Pulsed Radar Techniques

Instantaneous airborne determination of the thickness or layering of terrain material, especially floating ice, is feasible by use of high-resolution, monocycle radar. The analogy is to seismic-reflection prospecting using a single acoustic pulse, in that a single electromagnetic pulse (monocycle) is radiated into the terrain and thickness determined by analysis of the reflected returns.

When a monocycle is transmitted, a portion of the energy is reflected at the air-surface interface; the remainder is transmitted through the medium, and some of this is again reflected at the next interface. The latter might be a layer of soil having a different density or moisture content, such as the water table, the top of bedrock or permafrost, or the ice-water interface of floating ice sheets. Matching of the relative pulse amplitude and time delay to patterns prepared for the known physical properties of the medium being surveyed enables determination of the thickness or layering depth.

The period of the pulse is determined by the resolution required or the frequency range desirable. In general the lower frequencies can penetrate more deeply with less scattering, but at the same time are limited in time resolution for return signal interpretation. Pulses with central frequency of 400 megacycles and periods of several nanoseconds have successfully been used for this type of terrain sensing.

Barringer Research, Ltd. (Barringer, 1965) developed and tested such a system, using shock-excited antennas on a ground vehicle boom as shown in Figure 25, which accurately determined the thickness of the lake ice to within 10 percent.

Figure 25. Pulsed Radio Wave Method

Thickness and layering measurements of soils were less successful, due to the complex dielectric constant and conductivity relations within a soil mass. Additional tests indicated that variable-frequency radar operating at frequencies between 100 and 300 MHz, together with coincidence and correlation analysis of the complex pulse returns by computer techniques, would provide this capability. Barringer Research, Ltd. has recently developed an airborne version of this system for NASA that is awaiting verification tests. The Army Engineer Waterways Experiment Station has continued the work on the variable-frequency concept, using 300 MHz

frequencies on multi-layer soil samples. Absolute values of the soil dielectric constant were determined and the thickness of soil layers measured, even though the reflected power dropped to less than one percent due to surface roughness scattering or vegetation attenuation. Field tests by a ground vehicle-boom configuration are now being conducted.

The Adcole Corporation, under contract to the Army Terrestrial Science Center, has successfully continued the ice-thickness measurements, using a monocy- cle radar system from a helicopter (Meyer, 1966). Fresh-water ice masses up to a meter thick were measured, even with one-half meter of snow cover.

6.2 Radar Scatterometry

Radar scatterometry is an active remote-sensing technique pioneered by Dr. R. K. Moore at the University of Kansas under NASA sponsorship (Moore, 1966). It measures the radar scattering coefficient of surfaces having different roughness and material. Applications to measuring sea state and ice roughness were established, and indications of terrain texture and moisture content, both at the surface and somewhat beneath it, were observed. Scatterometry is feasible with wavelengths from fractions of a micron (using lasers) to tens of meters. The normal range for radar scatterometers is from a few millimeters to a few meters wavelength. This range by comparison is wider than from violet light to the longest infrared wavelength commonly in use.

Signals generated by a radar transmitter are re-radiated from the ground and received back at the radar location. If the ground surface is a perfectly smooth plane or sphere, a specular reflection results. Such surfaces almost never exist in nature, hence radar return is almost always a scattering process, enabling measurement of the scattering or reflectivity coefficient. The most favorable angle of incidence of an airborne radar scatterometer is near zero (normal incidence), as with larger angles the range is so great that signal return becomes too small for processing.

Normally, the radar scatterometer cannot discriminate individual small elements of the surface, but must look at a sum of the returns from many such elements. Processing of the data enables compilation of the differential scattering cross section that describes the average properties of a particular surface type.

Conclusions from experimental data gathered by the University of Kansas and Ohio State University with airborne radar scatterometers are that relatively smooth surfaces, such as the ocean, give strong returns near the vertical but the returns fall off rapidly with angle. Surfaces having the same geometry as the sea surface, but smaller reflection coefficients, such as deserts, have scattering coefficient curves with the same shape but smaller absolute magnitude. Surfaces

rough compared with wavelength, such as forests, or, for very short wavelengths, rough gravels, have smaller scattering coefficients near the vertical than the smoother surfaces. However, their scatter changes little with angle, so that near grazing the return from the rough surface is much greater than that from the smooth surface.

Both experimental observations and theory indicate that returns near the vertical are due to larger scale fluctuations in the surface than the returns near grazing angle of incidence. Detailed curves for specific materials have been prepared, including vegetated surfaces. Radar scatterometers provide their own illumination and can, therefore, discriminate among returning signals that are not dependent on self-emission or randomly incident sources reflected from the surface.

7. IMAGERY ANALYSIS TECHNIQUES

Skilled interpretation of sensor imagery, particularly photography but also including infrared-scanner and side-looking radar imagery, is the standard and most widely used method for identifying and evaluating earth surface features. The variation of the individual ability and experience of photointerpreters obviously affects imagery analysis, and efforts to improve upon such often subjective techniques are a necessity. Photointerpretation has generated a great variety of coding keys of terrain and cultural features, signatures, and backgrounds. However, these keys are used mainly to help an interpreter discriminate targets from the terrain background, whereas the objectives of remote sensing, as indicated in this report, are to provide knowledge of the properties of the "background" itself.

The University of Michigan is conducting (for the Air Force Avionics Laboratory) a target-signature program wherein they will compile, tabulate, and evaluate as much electromagnetic sensor imagery as possible pertaining to target discrimination and terrain characteristics. The NASA Manned Spacecraft Center in its Earth Resources program has also accumulated a vast library of sensor records of the character and composition of landforms and features of the earth's surface.

Many techniques are in the process of development, test, and application to ease the problems of manual interpretation of large amounts of sensor imagery and returns. Recording on magnetic tape allows a larger dynamic range of input signals and facilitates later processing of such imagery for enhancement of detail and contrast. The use of thermoplastic tape, pioneered by the General Electric Company, allows real-time recording up to densities of 1700 lines per inch with picture elements of 8000 per line (AFAL, 1966). The recording is done by an electron beam writing on a strip of 70-mm thermoplastic tape.

Electronic instrumentation for scanning imagery now permits the presentation in a graphical form of the gray-scale tonal values along the scanned traverse. Such waveform segments can be presented as statistical parameters associated with the various terrain types or characteristics recorded on the image. Many commercial and university groups have published descriptions and uses of such instrumentation for pattern-recognition objectives.

The color enhancement or color-additive technique is an excellent tool in photographic imagery analysis, particularly with multispectral images. Using this technique, for example, a negative is prepared from band 1 and a positive from band 2. By superimposing these, a complete cancellation is achieved except — a highly significant point — for those areas where a color difference exists in nature. A more sophisticated step is to prepare various combinations using many bands, such as a red, a blue, and a yellow band. In each case the film records emphasize color difference and subdue color likeness. When these records are cascaded and printed as a single unit or with additive printing onto a final color positive, the resulting image brings out features indistinguishable in any of the original film records. The appearance is that of a camouflage-detection image, and it emphasizes the otherwise subtle tonal differences discerned by the camera.

Optical data processing is a relatively new method that enables extraction of detail and contrast from photographic negatives. The development of fiber optics and the laser has sparked many applications of digital optical systems to data processing, pattern recognition, and analog computation. A major advantage of digital optical systems is their high storage density. Such systems enable the obtaining of many successive two-dimensional Fourier transforms of any given light-amplitude distribution, such as would be represented in aerial photographs of the earth's surface. The applications of optical data processing to geologic imagery interpretation and enhancement is currently under study for AFCRL by the University of Michigan. The appreciation of the imaging properties and vast storage density of holograms is an outgrowth of these experimental studies of reconstruction and analysis of imagery. However, lack of qualitative measurements and limiting conditions of image reconstruction have handicapped the use of holography, except in the laboratory.

Change detection, or the analysis of differences between two sets of imagery taken of the same area at different times, can show such factors as seasonal effects on terrain, growth of vegetation, and the sequential morphology of landforms, in addition to the militarily important changes in man-made or cultural features. Photographic or electronic images can be scanned, rectified, manipulated, and correlated by existing techniques, and evident changes can be automatically compared and recorded.

The Army Engineer Topographic Laboratory has developed an "automatic mosaicker" that produces rectified transparencies from imagery and compares them for change-detection purposes, rejecting extraneous factors such as clouds and shadows. Vertical images obviously have the greatest potential for treatment and analysis by this technique. Further extension of the change-detection concept to the "moving target indicator" are well developed and generally used in radar and active sensor reconnaissance and will not be treated in this report.

8. PASSIVE MICROWAVE RADIOMETRY

All objects emit electromagnetic energy due to the random thermal agitation of the electrons within them. The intensity of this radiation depends on the temperature of the object, the frequency at which it is measured, and certain of its physical properties such as dielectric constant, magnetic permeability, electrical conductivity, and surface characteristics. An object may also absorb or reflect any electromagnetic radiation that is incident upon it. The radiometric temperature of an object thus not only is dependent on its emissivity and own temperature but also on its reflectivity and the temperature of the sky environment being reflected.

The radiometric energy emitted from an object or material can be measured at great distances. In the microwave and millimeter wavelength regions the power emitted varies directly with its temperature and inversely with the square of the wavelength. At a given frequency and polarization the emissivity and reflectivity of a material are functions of its surface roughness and the angle of incidence of the radiometer antenna. The region of a solid object that contributes to its observed radiometric temperature extends from the surface downward to a depth depending on its dielectric constant and conductivity. Different frequencies can therefore be said to have different penetrations. Materials such as water or metals have high reflectivities and generally exhibit cold radiometric temperatures (150°K). Conversely, good absorbers such as dry soils or vegetation show high radiometric temperatures (290°K).

Passive microwave radiometric sensing of the apparent temperature of natural terrain and objects upon it is a previously neglected technique. With the development of new analytical methods, advanced instrumentation, and data processing techniques, this sensing method can now be effectively employed for ground-based and airborne earth-science studies. Raytheon Corp., North American Aviation, Inc., and the Jet Propulsion Laboratory of the University of California have used microwave sensing for several years and reported extensively on its applications.

Probably the most comprehensive application of passive microwave sensing of the properties of terrain is being conducted by the Space General Division of Aerojet General Corporation in a tri-service-supported study (Kennedy et al, 1967; Kennedy and Edgerton, 1967). From a boom on an extensively instrumented trailer, a three-frequency microwave radiometer with both vertical and horizontal polarization capability was successfully used to determine the moisture content, layering, and distribution of soils, water, ice, snow, and rocks. An example of the discrimination of soil types on the basis of their radiometric temperatures thus obtained is shown in Figure 26. Soil moisture content can be identified to a 1 percent accuracy by this technique.

Airborne passive microwave radiometric sensing is also a valid technique. Test flights of one of the Space General Division's radiometers over the terrain previously studied have closely verified the previous measurements. Icebergs and floating sea ice were detected by the U. S. Coast Guard for several years, using microwave equipment developed by Sperry Rand (Roeder, 1967).

Microwave thermal imaging of terrain is still a technique awaiting advanced equipment development. Space General conducted experiments using a 3.2-mm (94 GHz) radiometer (Chalfin and Ricketts, 1966). The output, as recorded on magnetic tape, was processed by a computer and plotted to yield half-tone images. Although appearing crude to the eye trained for photographic-image analysis, they showed gross terrain features that closely corresponded to visible-light photographs. The contrasts between reflectors and absorbers was strong, and in heavy fog, where visible and infrared photographs showed practically nothing, a useable image was produced by the radiometer.

9. VAPOR AND TRACE MATERIAL SENSING

Remote sensing of odors, gases, and vapors has recently been applied for personnel detection by the "people sniffer" developed by the Army Limited War Laboratory, and successfully used in Viet Nam. Another obvious use of such a technique is the conduction of air pollution studies. The measurement of vapor concentration by remote sensing is also potentially useful for geophysical exploration. Geothermal and volcanic activity often give rise to emanations of sulphur dioxide and halogens in the air, which can readily be of significance as indicators of sources of power, heat, and minerals, as well as potential hazards to military or geophysical installations.

Figure 26. Passive Microwave Data on Various Natural Materials

Oxidizing ore deposits similarly generate vapors that might be detectable. The association of detectable iodine with deposits of marine origin, such as oil field brines, may be exploited. Iodine is also concentrated in marine organisms and plant life by a factor of 10^5 as compared to seawater. Such sensing of marine life could have important economic applications in the future.

Barringer Research, Ltd. developed and tested instrumentation for the remote sensing of vapors; the instrumentation has a sensitivity in the one part per billion range (Barringer and Shock, 1966). The design is based on a conventional spectrometer with its exit slit replaced by a "spectrum correlation" recording mask. These masks are pre-prepared for known gases or vapors and used to cross-correlate the maxima and minima absorption bands of incident light from the gas being sampled. Laboratory tests have verified the sensitivity of the instrumentation and the feasibility of detecting and identifying low concentrations of sulphur dioxide, mercury, and iodine. An airborne unit has been built for NASA. It features an automated mask changer which programs the device for a number of specific vapors to be sensed and identified. Very high sensitivity for monotomic vapors can be obtained, due to the strong and narrow absorption lines they produce in a spectrometer.

The Army Ballistic Research Laboratory developed techniques for the rapid interpretation and discrimination of characteristic chemical vapor signatures by computerized pattern analysis. Such a system might be used with suitable sensors in low-flying aircraft to collect information about ground sources of such material.

10. LASER APPLICATIONS

So that low-light-level TV or scanning sensors can be used at night to view terrain or targets, laser illumination techniques are under development and even now being tested in actual operations. Such lasers radiate mainly in the infrared region. Problems foreseen are the need for stabilized systems to overcome aircraft buffeting by turbulence and the possible degradation of laser illumination by dust, smoke, or clouds. Also, the high repetition rates of a laser illuminator require more reliable and better cooling systems than do less sophisticated scanning assists.

A laser line-scanning camera used as a hightime reconnaissance sensor has been extensively tested (Stein, 1967). Such a sensor uses a laser beam scanned at right angles to the aircraft flight direction as a light source to illuminate the terrain below. The laser returns, varying as a function of the terrain reflectivity, are recorded on film with very high quality imagery resulting. Such a system eliminates the need for flash cartridges or other giveaways of the position of the photographic aircraft.

11. AIRBORNE PROFILE RECORDERS

The microtopography or surface roughness of terrain is of obvious importance in planning or conducting military operations. Natural obstacles such as bushes, boulders, or gullies complicate the evaluation of normal slope variations. When Arctic regions are considered, the ever-present pressure ridges and the irregularities of sea ice, glaciers, and ice fields are natural hindrances to wheeled vehicle traffic. Other needs for airborne surface roughness measurement are information on sea state conditions, wave heights, beach slopes, etc.

For many years, combinations of radar and barometric altimeters were used for relative terrain height measurements. These devices, commonly called airborne profile recorders, use the principle of radar reflection over aircraft-to-terrain distances, corrected for aircraft altitude deviation from some barometric datum surface. A reference is established by flying at a pre-set barometric altitude over a terrain feature of known elevation. Further flying over an area of interest will enable applying the aircraft altitude deviation to the radar height record to give the terrain profile. Primary limitations are accuracy (about $1 \text{ ft} \pm 0.5 \text{ percent}$ of flight altitude) and beam size (15° half angle). Present narrow-beam airborne profile recorders are estimated to have an accuracy of $\pm 20 \text{ ft}$ at altitudes up to 30,000 ft, while illuminating an area 500 ft wide.

A recent joint development of Aero Service Corp. and Spectra-Physics, Inc. has provided an operational laser altimeter with greatly improved accuracy and resolution performance (Jensen and Ruddock, 1965). This device incorporates an improved barometric pressure sensor with a CW helium-neon gas laser generating 50 mW of diffraction-limited light at 6238 Å. The beam generated is about 1 in. wide, resulting in terrain height resolution of 2 in. in the vertical plane and less than 1 ft in the horizontal at 1000 ft altitude, and within 2-5 ft vertical resolution at 15,000 ft altitude. Flight tests conducted under the auspices of the Army Engineer Waterways Experiment Station verified the exceptional ability of this device for terrain profiling. A limitation to all-weather use of this laser altimeter is the severe attenuation and scattering of the light beam by water vapor.

12. GAMMA-RAY SENSING

The gross natural gamma radioactivity of common sediments has been used for many years in mineral and oil exploration and in the interpretation of geologic structure. Marine shales have abnormally high radioactivity, whereas other rock types such as anhydrites, pure sandstones, and limestones have very low radioactivity.

The principal natural materials contributing to background gamma radiation are the uranium, thorium, and potassium decay series. Different soils and their parent rock material show varying and characteristic contents of these chemically different natural radioactive elements, which reflect the physics and chemistry of the rock in addition to the effects of weathering in soil production. In general, these element contents of igneous rocks increase with increasing acidity or silica content. These concentration ranges are tabulated in Table 2.

The U. S. Geological Survey (Moxham, 1960) has extensively explored mapped total gamma radio-activity patterns throughout the United States, using airborne scintillation counters. Major oil companies have done similar work in smaller areas. The recent development of practical, total-absorption, gamma ray, spectral-measuring equipment for field use has enabled much refinement of soil and rock identification by this technique.

The Army Engineer Waterways Experiment Station has conducted detailed laboratory investigations to determine soil parameters useful in estimating trafficability (USAEWES, 1967). Their results indicated that photopeak counts of the radioisotopes of primary interest were proportional to the moisture content of the soil samples; however, ratios of these photopeaks were nearly independent of moisture content, although different for each soil type tested. From this data, it would appear that geological formations, such as loess and shales, can be distinguished from limestone and sandstone material, and that this technique is a powerful tool for estimating soil moisture content. Airborne tests using a large array of gamma ray detectors were recently conducted to verify the extension of this sensing method for remote measurement.

13. AIRBORNE EM SENSING

Since a high proportion of the earth's sub-surface is covered by a mantle of soil, ice, weathered rocks, transported alluvium, glacial debris, dense vegetation, or water, airborne "prospecting" for subsurface deposits of minerals or strategic resources is limited to those deposits which have a surface expression. Airborne magnetic surveys are effective in outlining many types of intrusive and extrusive rocks, even when they are buried under deep overburden. However, these surveys are limited in defining the sedimentary geology wherein valuable ground water, non-magnetic metallic deposits, industrial minerals, construction materials, and oil resources may be residing.

Associated parameters such as conductivity, which can be sensed from aircraft, can provide useable clues to sub-surface deposits. The majority of metallic ores such as copper, nickel, lead, zinc, silver, and gold contain sufficient sulphides

Table 2. Radioactive Elements in Igneous Rocks and Sediments

RADIOACTIVE ELEMENTS IN IGNEOUS ROCKS			
Rock	Thorium (ppm)	Uranium (ppm)	Potassium (%K ₂ O)
Silicic Intrusive (Granites & Syenites)	1-25	1-6	1.5-6.0
Silicic Extrusive (Rhyolites & Trachytes)	9-25	2-7	
Basic Intrusive (Gabbros & Diabases)	0.5-5	0.3-2	0.4-3.0
Basic Extrusive (Basalts & Andesites)	0.5-10	0.2-4	
Ultrabasic Intrusives (Peridotites & Dunites)	low	0.001-0.03	0.1-1.0
RADIOACTIVE ELEMENTS IN SEDIMENTS			
Rock Type			
Clastic Rocks			
Common Shales	2-47	1-13	0.9-6.7
Orthoquartzites	0.7-2	0.2-0.6	0.9-2.6
Black Shales	2.8-28	1.4-80	0.9-6.7
Residual Rocks			
Bauxites	8-132	1.5-22	very low
Bentonites	6-44	1.0-21	very low
Precipitated Rocks			
Carbonates	0.1-7	0.1-6.5	0.1-0.6
Salt Beds	0.4-0.5	1-5	up to 30%
Chert	0.1-1.6	0.01-0.9	0.07-0.4

to provide them with a large conductivity contrast with surrounding rocks. The development of low-frequency, electromagnetic, inductive, airborne sensing systems has recently been exploited for commercial exploration. Present capabilities permit detection from several thousand feet altitude and signal penetrations up to 700 ft depth.

The U. S. Geological Survey is currently using an induced-pulse-transient EM system in an aircraft. This system radiates a short electromagnetic pulse that induces eddy currents in conductive bodies (Barringer, 1962). The pulse has a repetition rate of 380 pulses/sec, and is generated from a large horizontal loop antenna strung across the aircraft. The time-varying decay transients of the eddy currents are received in a stable high-drag "bird" towed behind the aircraft. The amplitudes of these received signals are sampled after selected time delays and their ratios define the shape of the characteristic decay curve associated with the degree of conductivity.

Initial use by the Canadian Geological Survey has indicated the ability of the system to detect gravel deposits, which could be important aquifers, lying in glacial clays (Collett, 1965). Computer analysis is being applied to study conductivity stratification in the ground. Results indicate that differentiation of areas of sulphide mineralization from those of other ionic conductors is feasible.

11. AIRBORNE MAGNETOMETERS

The airborne magnetometer has been used since 1946 in petroleum and mineral exploration, with some 20 million square miles of survey flown covering a large portion of the earth's surface. The military services have used airborne magnetometers for reconnaissance of submarines and land-vehicle targets. Gradual improvements in instrumentation have been made, but 1 gamma has generally represented the limit of attainable resolution.

Recently the rubidium vapor magnetometer was developed. Although originally designed to measure the magnetic field in space probes, it has had immediate use as an airborne device for oil exploration. The resolution of this device is 0.1 gamma, enabling more detailed mapping of the total magnetic field, which in turn reflects variations of the sedimentary structure and basement complex of the earth. The system can be located in a towed-bird configuration or mounted in a tail-boom "stinger" on aircraft. Data are presented on a strip chart in analog form, with the linear scale calibrated directly in gammas for easy compilation of area maps.

Further application of this new device has resulted in the magnetic gradiometer (Aero Service Corp., 1967), an ultra-sensitive tool for direct measurement of the vertical gradient of the earth's magnetic field. This system comprises two

simultaneously recording rubidium or cesium vapor magnetic sensors flown from or on an aircraft and separated by a fixed vertical distance. Sensitivity of measurement of the vertical gradient is in ten-thousands of a gamma per foot. In comparison to the total field map, the gradiometer more closely defines and differentiates earth structure effects and increases the amplitude of local anomalies while attenuating regional effects.

These new magnetometers also have application to the detection of buried objects, when used in ground-vehicle surveys. Arms caches, pipe lines, underground communication cables, etc., are susceptible to detection by this method, and it has been used recently in a presently inconclusive attempt to detect tunnels in Vietnam. Previous applications in detecting buried materials for archeological purposes have been reported.

15. GRAVITY SURVEYS

While airborne or surface measurement of the variations of the gravitational field over terrain areas cannot directly reveal the surface properties of such areas, these variations are often indicative of the geological formation beneath. In general, without delving into complex theories of gravity-earth structure relationships, it can be said that gravitational anomalies are related to the densities of underlying material. The average density of granitic rocks is about 2.7 gm/cc; for poorly-sorted fans and alluvial debris it is 2.4 gm/cc, and for silts, clays, or other fine material it is 2.0 gm/cc. Detailed surface gravity surveys may, therefore, give useful information on basement topography, the depth and extent of basin or fill material, the presence of faults as inferred from steep gravity gradients, and ~~barriers~~ to or channels for ground-water movement. In addition, sub-surface cavities or voids can be easily detected, since they appear as "negative" gravity anomalies of substantial size and extent (Romberg, 1961).

Because of the higher altitude and speed of coverage, airborne gravimetric surveys have far less capability to distinguish the density of terrain areas. However, experimental airborne gravimetric surveys are often used by commercial petroleum companies to outline large geologic structures, such as salt domes, that could be oil-bearing formations. Other large-scale regional features such as deep crustal rifts, major deep-seated igneous rock intrusions, and massive ore deposits may similarly be detectable, using the recently developed gravity gradient sensors of extremely high sensitivity (0.1 mgal).

16. ACOUSTIC SENSING

Acoustic sensing techniques are generally typified by the use of sonar to identify the location and spatial configuration of underwater objects such as submarines, mines, reefs, or structures. Some application has been made to sounding the bottomside of floating ice from submarines. However, airborne use of acoustic sources as sensors of terrain properties is generally infeasible. Limiting factors include the scattering of the sound through the intervening atmosphere, the wide-beam coverage of such a source, the scattering of a possible return, and the lack of acoustic coupling for propagation of sound waves through unconsolidated soils.

Sonar mapping of ocean bottom sediments and their distribution has been successful, using acoustic sources from a ship. Information on landforms adjacent to lakes, fjords, or rivers might be gained from a knowledge of the erosional materials deposited as bottom sediments. Sonic techniques deployed from a hovering helicopter having the necessary electric power capacity might also be used. One such commercial system generates a 0.5 msec acoustic pulse with extremely high peak pressure and a frequency of 1000 Hz. The reflected pulses are recorded on a moving chart to provide a continuous vertical profile of bottom characteristics. Analysis of reflection losses, ranging from 10 percent for hard sand to 90 percent for mud, might aid in determining the type and density of the parent material.

17. SEISMIC EXPLORATION METHODS

Seismic techniques obviously cannot be used in an airborne mode, but they do have application for ground-based terrain surveys. The seismic refraction method can be used to determine the depth to interfaces such as the water table, permafrost, bed rock, or sub-surface formations offering a distinct change in the propagation velocity of seismic waves. Delineation of deep-lying deposits is possible and qualitative relationships between seismic velocity and hydrologic parameters such as porosity and density have been established. Mapping of buried aquifers is therefore practical.

Now available are compact portable seismographs that utilize a hammer blow against a steel plate on the ground as an energy source. This eliminates the need for drill holes and explosives, and has greatly enlarged the utility of operation.

Some identification of the type of near-surface material is possible from computation of the wave velocity obtained by a thorough seismic refraction survey (Linehan, 1951). Dry, wind-blown sand or fine gravels have velocities varying from 1500 to 2500 ft/sec; heavier gravels with small amounts of clay binder run

up to 4000 ft/sec; while velocities from 4500 to 6000 ft/sec represent more compact gravels or those within the water table. Varved clays show a constant velocity of 5000 ft/sec, while values from 6000 to 9000 ft/sec usually represent a hard pan or till material that is heavy gravel and clay, often cemented together by iron rust or oxidation.

Rock velocities are not as reliable indicators of type, but in general low seismic velocities are associated with less dense or lower strength rocks.

18. ELECTRICAL RESISTIVITY MEASUREMENTS

Sensing of terrain properties by analysis of electric current propagation through the ground is a well-established exploration technique. Active transmission methods are generally used in resistivity measurements, while passive recording of telluric currents also provides information on sub-surface conditions. It is not feasible to generate or record such currents from the air, so these techniques would have no application in airborne sensing. However, field exploration using ground vehicles might well use electrical methods.

All surface and sub-surface materials have to some degree the ability to conduct an electrical current. The moisture within the earth's materials and, more particularly, the impurities in this moisture provide an avenue for the current flow. It is natural for the harder, denser, rock layers (containing less moisture and perhaps less impurities than the clays and silty layers) to have higher resistivities than fine-grained clays or silt. Salt water is a very good conductor of current flow. Hence, a geologic layer such as shale or clay, laid down under marine action, usually has a very low resistivity. Such materials can be located beneath weathered or leached-out materials overlying them.

Usually, any hard, dense layer of parent rock will have a resistivity that is different from its weathered components. Because of these and other characteristics, trial and calibration must be made over exposed or identifiable formations of each material to produce the type curves needed to evaluate data obtained from exploration.

The distance between the electrodes is a function of the depth of the area surveyed, as shown in Figure 27. By increasing the spacing, the test can be carried deeper, and any deep formation, such as solid rock, having generally higher resistivity than the surface layer, will be indicated by a rapid rise of the plotted curve. Tabulation and interpretation of measured resistivities can establish relationships of these to porosity, texture, salinity, and mineral content of terrain, in addition to defining the depth of bed rock, the water table, or permafrost layers.

INSTRUMENTATION

THEORY

Figure 27. Theory and Instrumentation of Electrical Resistivity

19. DROPPABLE SENSORS

To overcome problems of ground surveys, AFCRL (Molineux, 1955) and WES (1957-1963) developed several devices for airborne determination of soil strength, using projectiles dropped or fired from aircraft. Such an instrument, called an aerial penetrometer, is essentially an aluminum cylinder that looks like a small rocket; it is approximately 2.5 ft long, 2 in. in diameter, and weighs less than 2 lb. The original model was dropped from propeller-driven aircraft and had a spring mechanism to measure the impact. If the penetration resistance is greater than the pre-set level, a flare is released through the hollow barrel and rises to several hundred feet altitude as a visible "go-no-go" indicator. Figure 28 shows an exploded view of this device.

Figure 28. Assembly of Aerial Penetrometer

For tactical reconnaissance missions, an additional development by AFCRL facilitated an improved means of deployment and indication. This penetrometer can be ejected in quantities up to 10 in a pre-selected sequence from tip-tank launchers on jet aircraft at speeds of approximately 450 knots and altitudes of 1000 ft above the terrain. For multiple deployment the firing sequence is 0.5 sec apart, with the penetrometers thus landing about 300 ft apart. Ejection is by an electrically detonated charge contained within the launching system; the penetrometers are inert. They are nearly buried in their own holes, depending on the soil strength encountered, and are expendable. Soil hardness is indicated by the appearance of a self-contained light bulb visible through the vertically impacted cylinder. The launching mechanism shoots the penetrometers downward and backward at a component velocity sufficient to cancel the forward speed of the aircraft, so that the penetrometer hits the ground at 350 ft/sec directly under the spot where ejection takes place.

The penetrometer is aerodynamically stable with pop-out vanes governing its fall, which takes about 1.5 sec from ejection to impact. The strength-indicating mechanism is adjustable to allow determination of soil hardness through a range of values that might be required by various aircraft landing loads.

Development is now underway by AFCRL for another aerial penetrometer, operating on a depth of penetration principle, that is more pertinent to determination of relative strength differences in pre-selected areas. This device consists of two parts whose different weights cause them to separate on impact and transmit their relative displacement by radio telemetry.

The device, cylindrical in shape, has fins at the top to serve as an antenna and to provide aerodynamic stability. The cone-shaped bottom surface consists of the point of the penetrating cone and rod surrounded by a conical ring that is the impact surface of the penetrometer shell. It is about 24 in. long and less than 4 in. in diameter.

Relative displacement is transmitted by successive cutting of electrical wire pickups spaced along the shell length. Each cutting causes an increase in resistance of the circuit modulating the transmitter output, so the frequency of the tone signal increases with each cut. The depth of penetration is indicated by the number of step increases in the signal frequency; the uniformity of deceleration is indicated by their spacing. The signal from each penetrometer can be distinguished by an identifying code from a pre-set grouping of pickups. Figure 29 shows the configuration of this new development.

WES is currently developing and testing an air-dropped oscillator or dielectric penetrometer to penetrate or lie on the surface of the terrain for measurement and telemetry of the dielectric constant and conductivity of soils (USAEWES, 1966c). These parameters can be correlated to soil type and water content.

NASA has also conducted feasibility studies and testing of impact-type devices for determining the hardness of terrestrial surfaces (McCarty et al, 1964).

Figure 29. Modified Aerial Penetrometer With Telemetry Capability

20. IMPLANTED OR ROVING SENSORS

Implanted or air-dropped sensors for determining and monitoring meteorological conditions are well-developed and extensively used; the "Grasshopper" weather telemetry station is an example of this type sensor. Counterpart devices for monitoring sea state are in use by the Navy. Similarly, implanted sensors for determining hydrologic data are frequently used by the Army Engineers and the Department of the Interior.

A development effort sponsored by AFCRL at the Army Engineer Waterways Experiment Station resulted in an automated sensing station that can obtain and telemeter data on soil moisture, soil strength, and local weather variables from a remote site to a central headquarters (USAEWES, 1965). Purpose of the system is to provide information on landform conditions that might be affected by seasonal or climatic variations.

Soil moisture can be measured by electrical resistance sensors with a digitized microammeter readout or, preferably, by a neutron soil-moisture meter which would not be sensitive to possible effects of soil chemical composition on its resistance. Soil strength is determined by a hydraulic-loaded penetrometer operating at a constant penetration rate through a 2 ft depth. Obstruction would cause abandonment of the probe cycle and repetition at an adjacent location. The strength data can be recorded at the receiving station as an X-Y plot of force versus depth. Values of wind speed and direction, surface air and soil temperature, and precipitation falling on the site are also obtained and telemetered. The system can be actuated on a pre-programmed basis, on demand, or whenever rainfall occurs signalling a possible change in site properties of concern.

The station can either be permanently implanted or employed on a small track-laying vehicle that is self-propelled by battery power and guided with a cable attached to a central control mast about which the vehicle spirals. Telemetry can be by teletype or by radio link. All measuring sensors are transistorized, with automatic selection by logic circuits in the control unit. The teletype, in addition to paper-printing the data, also stores it on punched paper tape for possible future computer operations. The station and sensing system is capable of unattended operation for long periods of time at remote locations under extremes of temperature conditions. Figure 30 shows this penetrometer/vehicle system.

Figure 30. Remote Controlled Roving Ground Penetrometer Monitoring System

21. AIRBORNE SENSING LIMITATIONS

It is recognized that many limitations exist for full employment of types and arrays of airborne sensors. Many of these limitations are caused by the atmosphere intervening between the sensor and the terrain, such as air turbulence, absorption or attenuation of solar radiation by water vapor or ozone, cloud cover and rain, and lack of natural illumination for night photography. However, as the sensing wavelength increases, atmospheric absorption of the available energy generally decreases.

Some restrictions are due to the sensors themselves, including photographic resolution, non-linearity or distortion of camera film, and altitude or slant range limitations. Sensor operation in aircraft also presents problems of temperatures or pressure effects on the equipment, aircraft vibration, and requirements for size, configuration, electric power, and antenna placement. Degradation of photography through non-optical glass is another problem.

Still other limitations to efficient sensing and imagery interpretation are caused by the terrain and its topography. These include vegetation cover, surface scattering, shadowing, and man-made camouflage.

Some or most of these limitations can be overcome by proper design and planning of the sensing systems and operational missions, but they must always be considered.

22. DATA GATHERING VEHICLES

Useful terrain and environmental data can be obtained all the way from the earth's surface outward to space, ranging from sensors implanted below ground to manned or unmanned satellites.

The use of automated surface-based systems telemetering their data to a central headquarters has been well established. The gathering of seismic, gravity, magnetic or electrical data on earth properties by surface measurements is standard practice. Placing sensors on ground-vehicle booms or on platforms, towers, or arches enables obtaining "remote" surface data pertinent to the individual sensing technique.

The sensing vehicle most widely and successfully used is, of course, the aircraft. This vehicle combines the advantages of range, speed, and repetitive coverage with its capacity for containing large weights and volumes of sensing instrumentation and self-power generation. Sensing aircraft have ranged from helicopters and small observation planes through multi-engine reconnaissance aircraft to the supersonic X-15 type from which much photography has been obtained. Many governmental agencies (USGS, AFCRL, U. S. Department of Agriculture, and NASA in particular) have aircraft permanently instrumented and used for terrain property sensing. In addition, many commercial organizations have aircraft devoted to the mission of testing, verifying, and applying remote sensing instrumentation. Also, many universities, especially those conducting sponsored research in the earth sciences, operate well-equipped aircraft for data gathering assignments.

High-altitude balloons offer an intriguing potential for photographic or other sensing of terrain, as they provide a stable, vibration-free, and relatively controlled platform with slower passage over the ground than either aircraft or rockets reaching comparable altitudes.

Much earth photography has been obtained from past sounding rockets such as the Viking and Aerobee, and the Mercury series of satellite flights started a vast library of earth photographs obtained from space. The GEMINI series in particular has provided considerable information on terrain characteristics and mapping.

IV. Applications

I. INTRODUCTION

The success of a military air or ground operation is frequently dependent upon the proper utilization — that is, application — of terrain. The elements and parameters of the terrain that are pertinent to its proper utilization include its dimensions, composition, form, and dynamics. The terrain factor-effect relationships are, of course, not known for all military activities and must be determined by controlled performance testing. The ability to select an alternate terrain is necessary to meet any changing tactical situation or environmental elements.

Relevant military applications pertinent to terrain analysis include: strategic and tactical planning, air and ground navigation, and guidance, geodetic control, and target location; reconnaissance, surveillance, and detection of activities including perimeter intrusion, tunnels, and nuclear tests; intelligence; mapping and charting; site selection of bases, airfields, missile silos, roads, and surface and underground facilities such as command and control centers; location of sources of power and construction materials; aerospace craft and vehicle trafficability; analogous area analysis; design of weapon systems and destruction effects; surface modification and soil stabilization; prediction warning and protective measures against terrain movement and natural catastrophic events (earthquakes, volcanisms, landslides, floodings, tidal waves, and major erosive actions); and inducing actions

to degrade the capability of an enemy by causing landslides, flooding, and the instability of structures by inducing loss of strength in terrain foundations materials.

2. MODEL CRITERIA

Adequate quantitative terrain data incorporated into performance-prediction mathematical models are required for each terrain application. Essential lacking data would then be easily identified for required input to the model (WES, TR3-726, Vol. 1).

When the critical value limits of the terrain factors selected for input to the model change, the model must be modified. The data obtained from pilot-performance testing of the activity on terrain determines the critical values that are fed into the model concept.

Performance results are introduced into the analytical model to determine design criteria. These criteria are then translated into factor values representative of global environmental characteristics and are reflected in the design of new equipment and system components.

3. SELECTED TYPES OF APPLICATIONS

The applications described below are typical, since they relate to common operational problems. They are: trafficability, surface modification, analogous areas, and site selection.

3.1 Trafficability

The maneuverability of vehicles and aircraft on natural surfaces is based on the pedologic, geologic, hydrologic, physiographic, climatic, vegetative, and bearing strength properties of the terrain. An evaluation of all these elements of a terrain contributes to the rapid assessment of the conditions that will affect trafficability (U. S. Army WES, 1954, p. 9; U. S. Army WES, 1961, p. 10; AFM 88-51, p. 92; Pressman, et al, 1961; Needleman, 1962).

A terrain is considered trafficable when the forward thrust of a vehicle overcomes the rolling resistance at a specified rate of speed (Burns, 1960, p. 15). Certain soils in a comparatively dry state can be trafficable for many vehicles and aircraft (Womack, 1965).

Predicting the speed of vehicles along a planned route is dependent upon adequate available pertinent factor value data.

3.2 Surface Modification

Most surfaces require some modification for operational use; these modifications can be achieved through mechanical or chemical means. Standard construction procedures and equipment can prepare any surface for use by removing obstacles, substandard soil, vegetation, and rock horizons in the profile, and replacing them with suitable local indigenous materials (Needleman, 1961, p. 38). The properties of a soil may be improved by compaction, moisture control, blending of added materials, and stabilization. In the case of airstrips, the placement of landing mats and plastic membranes over a reinforced soil is widely practiced. A combination of these methods and concrete or asphalt surfacing is the optimum approach to improve a natural surface for a great deal of traffic (AFM 88-52, p. 175; U. S. Army WES, Misc. Paper 3-605, p. 3).

3.3 Analogous Areas

The use of accessible analogous terrain for conducting studies and tests substitutes for the inability to conduct such activities at the scene of anticipated operations. The comparison of similar areas requires the establishment of the factor classes upon which the analogies will be based. Although no area is entirely coincident, it is possible to identify areas that are nearly similar in the majority of the factors. These areas may have had an identical geologic and climatic history influence a similar development of their soil, vegetation, and topographic characteristics, resulting in approximately equal terrain factor values (Van Lopik, and Kolb, 1959, p. 3; Wood and Snell, 1960, p. 15; Curtis, 1966, p. 134).

In a case study of analogous areas in an arctic environment, 46 terrain sub-factors were considered for a determination of a suitable military test site.*

Research, development, engineering, and testing on selected sites in the U.S. that are analogous to other world environmental conditions are standard procedure in programs sponsored by Department of Defense agencies. The lack of completely analogous test sites results in some inaccurate performance data, but a range of values can be deduced to indicate the limits of each factor class in the design parameters (Stoertz, 1961, p. 7; Grabau, 1967a, p. 4). Worldwide conditions

* The factors may be characterized by slope or relief; elevation; vegetation type, density/height, tree trunk diameter; soil profile; rock type, strength, and structure; depth of thaw; depth of frost; depth, thickness, and continuity of permafrost; depth to water table; soil shearing strength; snow cover depth and density; river depth and velocity; stream width and bottom conditions; flooding; seasonal icings; slides and mudflows; earthquakes, volcanic activity; thermal factors (ground temperature, freeze-thaw index, and mean annual temperature); and miscellaneous environmental factors between terrain and climate (duration of darkness, blowing sand and dust, blowing and drifting snow and ice crystals).

are analyzed to develop optimum design criteria and provide a minimum number of limiting conditions for maximum utilization (Van Lopik and Kolb, 1959, p. 11).

3.1 Terrain Studies

So that alternate choices are available in the event of contingency action, the military is conducting continuing terrain studies throughout the world. This is being done so that extensive pre-mission reconnaissance will be minimized.

3.4.1 SITE SELECTION

The investigation of the earth's surface and subsurface for the location of airfields, roads, radar and missile sites, storage depots, and other facilities on all types of terrain (soil, snow, ice, permafrost, coral, laterite, etc.) is essential to successful global operations. The tactical situation in limited wars invariably demands the deployment and operational use of sites with marginal conditions in remote areas (Needleman, 1962, p. 69).

The terrain requirements for a specific mission determine the type of data needed for analysis. Each terrain factor in the model is evaluated for the application. Figure 9 outlines these sequences and shows the approach in arriving at recommended solutions for the decision-maker or commander.

4. APPLIED EARTH AND RELATED SCIENCES

The scientific areas that offer an insight into regions lying above and below the surface of the earth are geology, geodesy, geography, hydrology, glaciology, soil mechanics, soil science, soil engineering, geomagnetism, seismology, oceanography, ecology, biology, and electronics (AFM 88-53, p. 1; Strahler, 1963, p. 1; Strahler, 1960, p. 287; Berkner, 1962, p. 2180).

The data on the parameters peculiar to each application are correlated with data from these interrelated disciplines to draw reasonable conclusions from observed phenomena. Unfortunately, reports are usually issued in the major field of interest, incorporating only the terrain data applicable to that field of interest.

5. TERRAIN ENGINEERING

Engineering history is marked by failures of structures such as dams, bridges, tunnels, reservoirs, highways, and airfield runways due to weak foundation materials, faulty design, or excessive loading on the structure and associated earthwork construction (AFM 88-53, p. 191).

Of the various terrain features that commonly present engineering problems, rivers present the most severe problems. Plains and plateaus, on which most large operations take place, do not present as many severe problems. Hills and mountains are general obstacles and only suitable for small operations (AFM 88-53, p. 146).

Flood control and construction of foundations over permafrost, coral, or laterite present special problems. The construction of underground installations in consolidated and unconsolidated materials necessitates different techniques and equipment (Nat. Acad. of Sci., 1963).

As the effects of climate are more pronounced in an arid, tropical, or arctic environment, compared to a temperate zone, construction in these areas present unique problems.

5.1 Natural Resources for Military Operations

Indigenous construction materials and a useable water supply are essential for successful military applications. Purification of the water may be necessary when pollution, salinity, or minerals are found in the source of supply (AFM 88-53, p. 270).

BLANK PAGE

V. Research and Development Status

1. INTRODUCTION

The acquisition of subsurface data, particularly by remote methods, is not keeping pace with the requirements for quantitative terrain information (underground sites). Modern ground-test techniques can be used to expeditiously determine the suitability of a terrain, in any environment, for various uses, but airborne techniques have not yet been fully developed for operational use.

Gaps in our knowledge concerning the static and dynamic behavior of natural materials are being studied, and laboratory and field experiments are being conducted to evaluate the theoretical results.

Comparative methods of analyzing terrain parameters of analogous areas and the formulation of rigorous mathematical terrain models of global environments are attaining increased accuracy for operational utility. Key terrain characteristics can be evaluated, but the analysis of microfeatures requires supplementary sources of information from ground data, indirect measuring techniques, photogeologic analysis, and photogrammetric processing. Computer assistance is necessary to permit the rapid interpretation of terrain data and requires the development of programming methods for reducing data to a suitable matrix format (Figure 31).

Figure 31. Simulated Terrain Data Processing Approach

Terrain characteristics and the properties of soil, ice, and snow have been intensively studied by the Air Force, Army, and Navy. Terrain in polar, temperate, and desert environments was the major research interest in the past, but present research is concentrating on vegetated surfaces and landforms in a tropical environment, especially on the identification and measurement of the effects of vegetation on military operations and the exploitation of natural terrain.

2. CLASSIFICATION OF THE ENVIRONMENT

Techniques are being developed for classifying geographic areas and their respective subordinate physiographic regions in more quantitative terms, so that their effects on military operations can be evaluated. Such data are the basis for comparing one area with others that are similar in the majority of environmental parameters (Strahler, 1963, p. 326).

The Army's Waterways Experiment Station (WES), Terrestrial Sciences Center (ATSC), and Natick Laboratories (USANL) are improving methods for classifying and correlating the environments with the terrain. Sites in a particular environment are selected in accessible terrain and are representative of other areas

of the world where there is a possibility of future military activity. The terrain factors are analyzed and the resultant data utilized to optimize equipment design (Wood and Snell, 1960, p. 2; Grabau, 1967a, p. 3).

3. TERRAIN RESEARCH

Problems relative to the identification of terrain parameters and instrumentation and methodology for measuring those parameters are being studied by AFCRL, AFWL, ATSC, USANL, USAEWES, and ONR. These organizations are shifting a portion of their concentration from contact to remote sensing techniques for obtaining terrain data.

Data obtained from contact and non-contact methods are correlated and synthesized for application to military activities. As each study produces data for a particular use, an intensive analysis is done from a narrow perspective.

A comprehensive terrain research program of military significance has not been undertaken, although a number of efforts by DoD and their contractors have produced valuable data. These investigations resulted in the development of several terrain classification systems, but some gaps still exist and additional research is warranted. Some of these gaps are presently being studied by many organizations in the following areas.

3.1 Geology

Studies of geologic processes are being made to determine the static and dynamic properties of individual landforms and materials. This type of information is being applied to problems that include site selection of airfields, stability of underground structures and miscellaneous types of facilities, rapid excavation for the construction of military installations, location of natural hazards and power sources, and crustal studies for the detection of underground objects and communications.

3.2 Geophysics

Research on seismic methods for monitoring the earth's interior is being carried out in an effort to improve our ability to detect underground nuclear explosions. With improvements in seismic techniques and the necessary instrumentation, other tactical applications are possible (Bates, 1962, p. 2207; AFCRL, 1967, p. 280). Detailed gravimetric, magnetic, seismic, and geothermal studies will enable us to predict eruptions of volcanoes, to better understand the mechanisms involved in volcanic eruptions, and to utilize the energy associated with volcanoes, such as geothermal steam (Kiersch, 1964, p. 18).

The determination of site stability by geologic, gravimetric, and seismic methods offers great promise for monitoring earth movements on a continuous basis. With such a monitoring system, precautionary measures could be taken to prevent personal injury and damage to facilities from earthquakes and tsunamis (sea waves) (U. S. Coast and Geodetic Survey, 1964, p. 72).

3.3 Geodesy

Geodetic knowledge from improved ground, airborne, and orbital surveying techniques will redefine the shape of the earth, interrelate all points of the earth for better mapping and navigation accuracies, and refine astronomic and terrestrial constants for inertial guidance and new navigation systems. The areas of increased knowledge will include more accurate data on: undulations of the geodetic ellipsoid network of the earth; deflections of the vertical gravity component; the composition, thickness, warping, and rigidity of the crust, mantle, and the core of the earth; the movements of large land masses; the precise location of the magnetic and geographic poles; and response of crust to tidal accelerations, degree of crustal isostatic equilibrium, oceanic swell and tide cycles; all major gravity anomalies and equipotential surfaces up to satellite altitudes (Williams, 1963, p. 3; AFCRL, 1965, p. 135; AFCRL, 1967, p. 289).

Star catalogues are being refined to more accurately show their positions and motions. Research regarding the precise determination of astronomical constants is being continued. The moon and its precise librations are being studied, and large scale mapping, sufficient for precise reference in space and planetary exploration, is progressing (Williams, 1963, p. 4; Strahler, 1963, p. 71).

3.4 Geomagnetism

Studies of the earth's magnetic field (main field and transient magnetic variations) are continuing. The main field category includes magnetic surveys, magnetic charts, secular changes, rock magnetism, magnetic anomalies, and studies regarding its origin. The transient variations of the lunar, solar, and magnetic field are being investigated to develop more accurate world navigation charts (AFCRL, 1960, p. 10-1).

Correlations of magnetic field measurements from rockets, earth satellites, and space probes with those obtained on the ground is expanding our knowledge of the geomagnetic field and the internal composition and structure of the earth (Strahler, 1963, p. 142).

4. SOIL MECHANICS

Research is directed toward the maximum utilization of soils for military construction purposes.

Efforts are planned to advance the understanding of the static and dynamic characteristics of soils under varied loads. Methods are being developed to predict the profile and engineering properties of soils in order to determine the needs for final site selection and utility. Accompanying these efforts is the search for improved sonic, electrical, electromagnetic, seismic, and radioactive techniques for rapidly measuring soil properties. Soil models and analog techniques are being applied to predict the trafficability of global terrain. Research will be continued on the response of soils and rocks to high-energy impulses (Tsai, 1967, p. 33).

5. REMOTE SENSING

Ultraviolet, polarization, and passive microwave sensing techniques are being studied to provide interpretable imagery of terrain data. (Figure 8).

New applications of existing techniques are being developed, and the instrumentation is continually being improved. Radar scatterometry, multi-spectral photography, and passive microwave thermal imaging are representative areas that have been improved by advanced instrumentation development (USAF Scientific Advisory Board, 1966, p. 12).

Research toward the development of a semi-automated terrain-data-interpretation process has recently been initiated. Pattern recognition, spectral discrimination, and mapping by computer printout of terrain characteristics are potential areas of application needing much further investigation. Advances in fiber optics may enable an automated generation, presentation, and comparison of the terrain data with imagery presently available. The tape recording of sensor outputs permits automated enhancement, storage, and contrast comparisons that far exceed the dynamic range of present photographic film (Van Lopik, 1962, p. 777).

The continued growth and refinement of a data bank of target and background signatures is sorely needed. Such reference information will guide the test, interpretation, and application of new imaging sensors by providing ranges of exposure settings for optimum sensor use. Discrimination of land contours, spatial extent, and spectral reflectance of material composition, using such data bank information, could enhance the detection and interpretation of natural backgrounds and penetrate possible masking or camouflage of targets.

The use of sensors in orbiting platforms is a new technique that is still in its infancy, but the vast potential of space photography has already been demonstrated by NASA. Research directed toward the use of other kinds of sensors in orbiting platforms should now be initiated in order to exploit their potentials. The repeated coverage of wide geographic areas of the earth's surface by orbiting sensors would be of obvious benefit for assessing changing conditions, seasonal, climatic, and otherwise.

6. SCIENCES OF MARINE ENVIRONMENT

Advances in oceanography (studies in marine gravimetric, magnetic, seismic, heat-flow, and the specialized interrelated disciplines of traditional science — geology, chemistry, biology, and physics) are refining theories on the earth's history and internal structure (Strahler, 1963, p. 292).

The potential fields of applications to be derived from studies in ocean technology are aircraft landing sites on floating sea ice, underwater missile sites, underwater storage and tank fields, salt water conversion processes, scientific waste disposal, trans-ocean pipelines, nuclear damage in water areas, predicting and inducing tsunami waves, mineral recovery and extraction, seafood farming, submarine navigation, etc. Methods for preventing beach erosion and harbor and waterways over-sedimentation are being investigated.

7. COMPUTERIZATION OF DATA

Data on terrain factor values will be computerized and used in controlled laboratory experiments, followed by field tests in varied environmental and terrain conditions. The data obtained from these tests will permit rapid analysis for comparison with the established criteria of specific uses (Anstey, 1960, p. 4).

Efforts are being made toward establishing guidelines for acquiring earth-science data that will be amenable to mathematical processing. Past records include errors that will remain until replaced by new data.

As a research aid, computer technology is a much more efficient use of geo-science libraries than the inadequate bibliographic procedures. For many years a need has existed for the automated tabulation of references and scientific data. Many libraries are awaiting the results of present research studies before incorporating such computer methods. The increasing volume and complexity of the scientific literature of military importance indicates the need for continued research in this area to improve data retrieval methods (Pangborn, 1967, p. 18; Miesch, 1967, p. 13).

VI. Conclusions and Recommendations

I. CONCLUSIONS

The success of global military operations is based upon the tactical exploitation of terrain in all environments. As terrain is a common denominator of earth science and the art of warfare, a multi-disciplinary understanding of terrain parameters in quantitative terms is necessary in modern technology. An efficient system of acquiring, quantifying, interpreting, and evaluating such data on a global basis is absolutely essential. The significance of terrain parameters varies with the use, but the instrumentation and methodology to collect the information are similar.

A combination of ground, airborne, and future orbital scientific techniques can be used to develop a "quick-response" type of capability for obtaining ground data and predicting use of terrain for specific military purposes. This capability could be further enhanced by the computerization of geoscience information and the development of methods for retrieving selected data for rapid synthesis and evaluation.

Advanced warfare concepts and recent conflicts have emphasized the inadequacy of our quantitative global terrain data. With our limited data, we are unable to perform certain operations on a routine, efficient, rapid, and automated basis. This problem has been partially solved by the introduction of electronic skills,

but problem areas still exist, particularly obtaining data below the surface of the earth. Scientific and technological gaps are only gradually being identified, delineated, studied, and surmounted by additional research and development, but research funds are limited. The only exception to this austere support occurs in the category of priority programs in narrow fields when requirements are established for special applications. The current state of knowledge is in the form of an incomplete foundation upon which new scientific information must be added from productive research, development, and test efforts.

Military-sponsored applied research has achieved some technologic progress in semi-automated terrain-analysis capabilities, but the progress has been slow and expensive. This approach has involved the use of research performed by private contractors. Certain problems remain to be solved for improved capability.

Microterrain data are not recorded for many parts of the world, and available data are plotted on small-scale maps that are inadequate for conducting all types of military operations. Critical terrain factor values for specific uses are difficult to predict without adequate measured data. This type of precise information currently must be obtained by ground methods of investigation. Remote sensing methods from aircraft and possibly from orbital altitudes could provide the necessary quantitative information, if an optimum terrain investigating system and advanced analytical techniques were developed.

Terrain problems that should be investigated by remote sensing technology are: bearing strength as a function of moisture, climate, vegetation, soil, and related parameters; resolution of microrelief; identification of type and determination of properties of complex soils (laterites, permafrost, coral); location of adequate water supplies; site selection for natural landing areas; detection of clandestine nuclear tests; determination of weapons effects; occurrence of natural catastrophic events above and below the surface (landslides, volcanic eruptions, tsunamis, earthquakes); micromovements; and rock failures in underground structures, affecting weapon system accuracies.

Although conventional aerial photography is presently the most reliable sensor for providing geometrical measurements and locations of terrain features, it is not possible to examine subsurface features directly from any film and filter combinations. Stereoscopic viewing of such photography can reveal much qualitative information on the microfeatures. Photography has a higher resolution of ground characteristics by an order of magnitude greater than current radar or infrared systems flown at comparable altitudes (Neal, 1965).

New films, improvements in photographic resolution and contrast, and techniques for recording spectral information from the near-ultraviolet through the near-infrared are providing methods for identifying terrain characteristics.

At wavelengths longer than 0.9μ , imaging on film is not presently possible. Various infrared, radar, and microwave line scanners can supplement photography to generate imagery interpretable in terms of terrain properties. Parameters such as surface planes of weakness (jointing, faulting, fracturing), lateral variations in soil moisture and ground water, and soil or rock types are susceptible to identification and discrimination from such imagery. To date, this interpretation is not reliable, but research and development regarding the origin and distortion of images with time, weather, aspect angle, or polarization will reduce the ambiguities in the interpretation.

The interpretation of remote sensor records has not kept pace with the development of the individual sensors. Development of the capability to correlate terrain properties with the characteristics of images or the electromagnetic energy levels received is progressing. The premise that each material has characteristic signatures at differing wavelengths, varying with the physical state of the material, is accepted in the scientific community. Identification of the materials and their engineering properties through diagnostic spectral characteristics analysis, supported by a minimum of valid and reliable "ground truth" data for correlation, will achieve a milestone in terrain-analysis technology.

With further research and development in computerized techniques, remote sensing will enable an economical compilation of the engineering properties of terrain for any area susceptible to overflight.

The development of an automated terrain-data-gathering and efficient display system cannot be achieved without adequate support to perform the basic and applied research needed for a modern level of competence.

The report has stressed the importance of the quality of terrain input data, the adequacy of an evaluation model, and the appropriateness of performance data in research, development, testing, and engineering. The recommendations listed below are designed to pinpoint those areas requiring more intensive investigation to alleviate the gaps in the advancement of terrain-analysis technology. Such objectives can be attained only by having complete knowledge of the pertinent terrain parameters and factor values. In the cases where data are lacking, an efficient and rapid information acquisition system is essential for an improved military capability.

2. RECOMMENDATIONS

2.1 Future work should develop an integrated method for describing the surface configuration of landscape patterns and correlating them with airborne sensor data.

2.2 Further study should be made regarding: the type of terrain data that can be derived from imagery for photogrammetric use, the correlation of "in situ" terrain characteristics with sensor imagery obtained from an airborne or orbital system.

2.3 A major effort should be directed toward quantifying terrain parameters for computer storage, retrieval, reduction, and data analysis in digital or analog form (Beckett, 1962; Wood and Snell, 1960, p. 11).

2.4 Work should continue on the development of a classification system for all types of terrain, water bodies, and hazards. The data should be in matrix format and applicable for varied military uses and for the conductance of analogous area studies (Beckett and Webster, 1965).

2.5 Assemble an atlas of indexed representative global landform and microrelief features with accompanying air and ground photos, other related imagery, and large-scale topographic, geologic, vegetation, and soil maps (Bredahl and Kiefer, 1957; Kiefer, 1957). Expand and update the "USAF Index to Aerial and Ground Photographic Features Throughout the World," dated 30 September 1946, Supplement No. 1, 2 January 1949, including newly discovered variations of landforms.

2.6 Continue performance tests of aircraft and ground vehicles on controlled natural surfaces to produce factor values for military mobility on natural terrain (Johnson, 1962; Tsai, 1967; Air Force Flight Test Center, 1963).

2.7 Implement a program for measuring, under controlled experimental conditions in the laboratory and field, the spectral reflectance properties of all types of earth materials, to determine atmospheric and visibility parameters influencing the reflectance measurements.

2.8 Continue the growth and refinement of a "target-signature" data storage repository (bank) containing data on the reflectance properties of specific terrain materials needed for the interpretation of sensor imagery obtained from laboratory, field, and airborne or spaceborne sensor platforms.

2.9 Continue efforts to develop automated methods for pattern recognition, spectral or spatial discrimination, image contrast enhancement, computer print-out of mapped imagery, and digital format for storage of sensor data.

2.10 Test the various sensors at balloon, rocketborne vehicle, and satellite altitudes to establish their capabilities and/or limitations.

2.11 Apply the available techniques of terrain analysis to siting of all major military installations, to provide the maximum engineering data, efficiency, and economic benefits.

3. SUMMARY OF KEY CONCLUSIONS AND RECOMMENDATIONS

3.1 Conclusions

Terrain is a common denominator of earth science and art of warfare.

Global terrain data are incomplete or lacking.

Ground and airborne data-acquisition techniques are available.

Orbital techniques are experimental.

Present and potential applications are numerous.

Remote sensing offers much promise in earth science research and development.

3.2 Recommendations

Develop better criteria for terrain evaluation.

Refine methods of measuring microterrain features and critical factor values.

Develop sensors with improved resolution for interpretation of microterrain factors.

Develop orbital methods of high resolution terrain sensing and data telemetry.

Develop automated methods of data storage, retrieval, processing, reduction, interpretation, and handling.

Acknowledgments

Appreciation for their coordination, review, and suggestions for improving this report is gratefully extended to Dr. William E. Davies, USGS; Dr. Max Britton, ONR; Mr. S. J. Knight and Mr. W. E. Grabau, USAWES; Dr. F. DePercin, USARO; Dr. L. W. Trueblood, USANL; and Mr. C. W. Molineux, AFCRL.

A special note of acknowledgment is made for the great patience and invaluable assistance of Mrs. R. M. Brown in the preparation of the manuscript of this report.

Glossary of Terms in Common Usage*

Acceleration of Gravity - The acceleration of a body falling freely in a vacuum due to the gravitational attraction of the earth. The International Committee of Weights and Measures has adopted as a standard or accepted value of $980.665 \text{ cm./sec}^2$ or 32.174 ft/sec^2 , but its true value varies with latitude, altitude, and the nature of the underlying rocks.

Active Layer - Annually thawed layer; layer of ground above the permafrost which thaws in the summer and freezes in the winter.

Adobe - An impure, calcereous clay widely used in the United States for making sun-dried bricks.

Age - Any great period of time in the history of the earth or the material universe marked by special phases of physical conditions or organic development; formal geologic time unit corresponding to a stage; informal geologic time unit corresponding to any stratigraphic unit.

Aggradation - The process of building up a surface by deposition; the growth of a permafrost area.

Aggregated - To bring together; to collect or unite into a mass; composed of a mixture of substances, separable by mechanical means; the mineral material such as sand, gravel, shells, slag, or broken stone, or combination thereof, with which cement or bituminous material is mixed to form a mortar or concrete.

Airborne Scintillation Counter - Any scintillation counter especially designed to measure the ambient radioactivity from an aircraft in flight.

Albedo - The percentage of the incoming radiation that is reflected by a natural surface such as the ground, ice, snow, or water.

*American Geological Institute (1960)

Alkali Flat - A level lakelike plain formed in low depressions where accumulated water evaporates depositing fine sediment and dissolved minerals which form a hard surface if mechanical sediments prevail or a crumbly powdered surface if efflorescent salts are abundant.

Alluvium - A general term for all detrital deposits resulting from the operations of modern rivers, thus including the sediments laid down in river beds, flood plains, lakes, fans at the foot of mountain slopes, and estuaries.

Angle of Repose - The maximum slope or angle at which a material such as soil or loose rock remains stable. When exceeded, mass movement by slipping as well as by water erosion may be expected.

Angstrom Unit - A unit of length of 10^{-8} cm., commonly used in crystallography.

Archipelago - Any sea or broad sheet of water interspersed with many islands or with a group of islands; also a group of islands.

Arid Climate - A climate in which the rainfall is insufficient to support vegetation.

Arroyo - The channel of an ephemeral or intermittent stream, usually with vertical banks of unconsolidated material 2 ft or more high.

Artésian Water - Ground water that is under sufficient pressure to rise above the level at which it is encountered by a well, but which does not necessarily rise to or above the surface of the ground.

Atmosphere - The gaseous envelope surrounding the earth; the atmosphere is odorless, colorless, tasteless, very mobile, flowing readily under even a slight pressure gradient; elastic, compressible, capable of unlimited expansion, a poor conductor of heat, but able to transmit vibrations with considerable velocity.

Atoll - A ringlike "coral" island or islands encircling or nearly encircling a lagoon. An atoll reef is a ring-shaped, coral reef, often carrying low sand islands, enclosing a body of water.

Avalanche - A large mass of snow or ice, sometimes accompanied by other material, moving rapidly down a mountain slope.

Backshore - Upper shore zone beyond the reach of ordinary waves and tides; one or more nearly horizontal surfaces called berms formed landward from the beach crest; may slope inland.

Badlands - A region nearly devoid of vegetation where erosion, instead of carving hills and valleys of the ordinary type, has cut the land into an intricate maze of narrow ravines and sharp crests and pinnacles. Travel across such a region is almost impossible; extremely rough topography formed in an advanced stage of gullying in poorly consolidated sediments and characterized by sharp-edge ridges separated by narrow and steep gullies.

Bajada - A nearly flat surface of a continuous apron consisting of confluent alluvial fans that make up the general slope in a basin; a series of confluent alluvial fans along the base of a mountain range.

Bar - A mass of sand, gravel or alluvium deposited on the bed of a stream, sea, or lake or at the mouth of a stream forming an obstruction to water navigation.

Barchan - A dune having crescentic ground plan, with the convex side facing the wind; the profile is assymetric, with the gentler slope on the convex side, and the steeper slope on the concave or leeward side; the barchan type is most characteristic of the inland desert regions.

Base Level - The level below which a land surface cannot be reduced by running water. Sea level is considered the principal base level. Principal streams serve as local or temporary base levels for their tributaries.

Basin - A region in which the strata or layers of rock dip in all directions towards a central point such as an inverted dome; a river basin is the total area drained by the river and its tributaries; a lake basin is the basin filled by water of the lake; any hollow or trough in the earth's crust whether filled by water or not.

Beach Berm - Nearly horizontal bench or narrow terrace formed by wave action in unconsolidated material on the backshore of a beach with surface rising behind it and sloping off in front.

Bedrock - The solid rock beneath the loose material, or soil and subsoil, with which most of the land surface of the earth is covered. It is sometimes several hundred feet beneath the surface, but it usually is found at a much smaller depth; in places, especially on steep slopes, it has no soil cover at all.

Bench Mark - In surveying, a mark, usually cut in stone as a relatively permanent material object, natural or artificial, bearing a marked point whose elevation above or below an adopted datum (such as sea level) is known.

Block Diagram - Three-dimensional perspective representation of geologic or topographic features showing a surface area and generally two vertical cross sections.

Bluff - Any high headland or bank presenting a precipitous front; it is usually applied to the slopes bordering a river; these bluffs often formed by the action of the river in cutting into the valley sides.

Bog - An area of soft, wet, spongy ground, consisting chiefly of decayed or decaying moss and other vegetable matter. It often forms in shallow, stagnant lakes or ponds, and is largely produced by sphagnum moss; the latter spreads out from the shores, floating on the surface, and gives a deposit of vegetable matter or peat on the bottom. A swamp or tract of wet land, covered in many cases with peat.

Bolson - A basin; a depression or valley having no outlet; a wide valley drained by a stream flowing through canyons at each end.

Caldera - A large basin-shaped volcanic depression, more or less circular or cirquelike in form, the diameter of which is many times greater than that of the included volcanic vent or vents, no matter what the steepness of the walls or form of the floor. Three major types: explosion, collapse, erosion.

Caliche - Secondary calcareous material occurring in a layer or layers at or near the surface. May be a soft or hard horizon of lime accumulation in the soil, but more commonly the term refers to a cemented layer a few inches to many feet in thickness containing impurities of clay, sand, or gravel. Most caliche deposits appear to form by a variety of processes whereby soil moisture evaporates or deposits its content of calcium carbonate.

Canyon - A gorge, relatively narrow but of considerable size, bounded by steep slopes.

Cave - A hollow space developed in a portion of the earth's crust. A sea-cave may be produced by the action of the waves and also by boulders and pebbles being thrown against a cliff by the sea. It may also be formed by the contraction and expansion of the air in a rock fissure as the waves advance and retreat. Inland caves are often formed in a limestone region where water containing carbon dioxide dissolves out underground channels and enlarges them in places to form caves, usually with a stream flowing through them.

Chain - A mountain system consisting of a collection of more or less parallel ranges, and possibly including plateaus, provided that the general longitudinal arrangement is maintained.

Chemical Weathering - The weathering of rock by chemical processes such as oxidation, carbonation, hydration, and solution.

Climatology - The science that treats of the various climates of the earth and their influence on the natural environment.

Coastal Plain - A plain that borders the sea coast and extends from the sea to the nearest elevated land. It is sometimes formed through deundation by the sea, the beach being later raised by earth movement to form a plain, frequently known as a Raised Beach, or by deposition of solid matter at their mouths by rivers.

Compaction - The increase in density of a soil mass by rolling, tamping, vibrating, or other methods; expressed as pounds of wet soil or dry soil per cubic foot.

Coniferous Forest - A forest of evergreen coniferous or cone-bearing trees carrying needle-shaped leaves. From such forests is obtained the valuable softwood timber of commerce.

Continental Drift - The supposed horizontal displacement of portions of the original continent that comprised the entire land mass of the world to form the present-day continents. It is described as Wegener's Hypothesis.

Continental Shelf - The terrace-like submerged surface bordering the continents, sloping gently and extending as far as 600 miles out under the sea.

Coral Reef - A chain of rocks lying at or near the surface of the sea and built up principally from immense numbers of skeletal marine creatures; both on and behind the reef, fragments of shells, coral, and coral sand are piled up by the wind and wave action, and new land is thus formed. Three more or less distinct kinds of coral reef are recognized: fringing reefs, barrier reefs, and atolls.

Crater - A steep-sided pit or basin, usually at the summit of a volcano, and formed when the top of the volcano was removed by explosion or collapse.

Crevasse - A deep, vertical crack in a glacier. Transverse crevasses develop across a glacier wherever there is a marked steepening of the slope of its floor. Longitudinal crevasses, roughly parallel to the direction of flowage, are formed whenever ice is obliged to spread out. Marginal crevasses point upstream from the sides of the glacier.

Deciduous Forest - A forest consisting of trees that lose their leaves at some season of the year. In the case of the monsoon forests, such as those of India and Burma, the trees shed their leaves during the hot season in order to protect themselves against excessive loss of moisture by evaporation. From the deciduous forests is obtained much of the valuable hardwood timber of commerce; the monsoon forests yield such extremely hard wood as teak, oak, elm, and beech from the cool intermediate forests.

Degradation - A process that tends to wear down the land surface; it is usually applied to a river and it involves the deepening of its valley by the river.

Delta - An alluvial deposit formed at the mouth of a flowing stream emptying into the relatively quiet water of a lake, sea, or ocean.

Dendritic Drainage - A tree-like arrangement of a main stream and successively smaller tributaries joining it at acute angles.

Deposition - The laying down in a new location of material that has been carried from another place.

Desert - An almost barren track of land in which the precipitation is so scanty or spasmodic that it will not adequately support vegetation.

Diastrophism - Deformation of the earth's crust by folding, bending, warping, or faulting.

Dome - A curved stratum of rock in which the slope is in all its directions away from a central point.

Drumlin - An elongated, half-egg-shaped hill made up of material deposited beneath glacial ice; it occurs in a previously glaciated region, the long axis lying parallel to the direction of flow of the ice, with the thick, steep end to the north.

Dune - An accumulation, as a hill or ridge, of windblown sand common from erosion in deserts. The sand particles are carried along by the wind and piled into a heap that gradually increases in size until it becomes a small hill; the dune is often commenced where an obstacle of some kind impedes the free movement of the wind. The sand is then heaped against the obstacle until it is covered. By the action of the wind, the shape and size of the dune are always changing.

Dust - Solid matter consisting of minute particles, smaller than sand particles, and occurring everywhere in the atmosphere; it is often carried immense distances by the wind, and is constantly being deposited on the earth's surface. The sources of dust are various: in and near to industrial areas, the smoke from factory and domestic chimneys charges the atmosphere with particles of carbon and other substances; in the deserts dust is raised from the ground by the wind while volcanic dust enters the air during an eruption.

Earth - The fifth in size of the eight major planets in the solar system, and the third in nearest distance from the sun. The solid outer crust of the earth, known as the lithosphere, is partially covered (72%) by an extensive area of water, known as the hydrosphere, and around the earth is a gaseous envelope known as the atmosphere. Although the earth is often regarded as being a sphere, it is actually an oblate spheroid, being slightly flattened at the poles; the polar distance is about 27 miles shorter than the equatorial diameter, that being 7,926 miles in length.

Earthquake - A movement or tremor of the earth's crust that originates naturally and below the surface, it sometimes causes a permanent change of level at the surface, but often the damage done by the shaking provides the only lasting visible effect. It may be produced by a volcanic explosion; earthquakes are common in most volcanic areas and often precede or accompany eruptions.

Ecology - The science that treats of organisms in relation to their environment; it is frequently subdivided into human ecology, plant ecology, animal ecology, and bio-ecology. Bio-ecology deals with the inter-relationships between animal life and plant life. Ecology lies on the frontiers of many areas including geography.

Equatorial Forest - (Tropical Rain Forest) The hot, wet, evergreen forest of the equatorial region, where rainfall is very heavy and where there is no dry season; it extends in parts into the typical monsoon areas. Because of the extreme heat and moisture, the growth is dense and luxuriant.

Erosion - The wearing away of the land surface by various natural agencies, the most important being those consisting of water — the sea, rivers, and rain. Ice, in the form of glaciers, frost, and melting snow also assists in the process of erosion.

Esker - A long narrow sinuous ridge composed chiefly of irregularly stratified sand and gravel. It was once the bed of a stream flowing beneath or in the ice of a glacier, and was left behind when the ice melted.

Estuary - A broad, shallow indentation of a coastline where the sea advances far up a river valley, inundating lowlands and permitting tidal currents to back up the river for some distance upstream.

Exfoliation - A weathering process that consists in the peeling off of thin layers of rock from the surface. In hot deserts it is caused by the heating of the rocks by day and their cooling by night, leading to alternate expansion and contraction. The corners of rock masses especially are broken off, and the surfaces assume a rounded form. The process is often assisted by others, such as the chemical weathering of the outer layers. The term "onion weathering" is sometimes used for exfoliation.

Fault - A fracture of the earth's crust along which movement has taken place.

Fauna - The animal life of a region or of a geological period, corresponding to the term "flora" for plant life.

Firn - Old snow that has lasted through at least one summer; the flakes have changed to grains of spherical shape that may or may not be bonded together. Firn may later become glacial ice.

Fjord - A long, narrow, deep, and steep-sided indentation of the sea along a mountainous coast, covering a sunken valley that was formed by glacial erosion.

Flood Plain - A broad expanse of land in a stream valley that was built up by the deposition of alluvium or sediment carried down by the river during the overflow of water.

Flora - The plant life of a region or of a geological period.

Frost Action - The weathering process caused by repeated cycles of freezing and thawing.

Geodesy - The science of the measurement of the size and shape of the earth and the surveying of large portions of the earth's surface.

Geography - The subject that describes the earth's surface - its physical features, climates, products, peoples, and their distribution.

Geoid - A term used to signify the shape of the earth, an oblate spheroid with certain variations.

Geology - The science of the composition, structure, and history of the earth. It includes the study of the materials of which the earth is made, the forces that act upon these materials and the resulting structures, the distribution of the rocks of the earth's crust, and the history, not only of the earth itself, but also of the plants and animals that inhabited it throughout the different ages.

Geomorphology - The study of the physical features of the earth, the arrangement and form of the earth's crust, and of the relationship between these physical features and the underlying geological structures.

Geophysics - The study of the physical processes relating to the structure of the earth, including not only the lithosphere but also the hydrosphere and the atmosphere. It signifies the physics of the earth linking the sciences of physics and geology.

Glacier - An accumulation of ice that has become so large that sufficient pressure is created to cause movement along the outer margins of the mass.

Gorge - A valley that is more than usually deep and narrow, with steep walls; there is no sharp distinction between a gorge and a canyon. The sides of a small gorge are sometimes nearly vertical.

Grasslands - Those regions of the world where the natural vegetation consists of grass; the rainfall is too light to permit forest growth, but is less scanty and irregular than that of the deserts; the grasslands are thus normally situated between the forest belts and the arid regions.

Gravel - A deposit of rounded stones, usually mixed with finer material such as sand or clay, formed by the action of moving water — by a river or a lake, or by the sea.

Ground Water - Water that has seeped below the earth's surface and occupies porous spaces in the underlying materials.

Ground Water Table - The top of the saturated zone in which ground water has completely filled the openings between individual soil and rock particles. Most of the ground water occurs within a few hundred feet of the earth's surface.

Gulch - A narrow deep ravine with steep sides formed by a torrent.

Gully - A long, narrow channel worn out by the action of the water, particularly in a hillside; it is smaller than a ravine or a valley. The term is often used of a channel produced in the erosion of soil; such a gully normally carries water only during or immediately after rain or the melting of snow.

Hardpan - A hardened or cemented layer of soil, impervious to drainage, lying below the surface.

Hot Spring - A stream of hot water issuing from the ground, often after being heated by buried lava, and commonly occurring in a volcanic region when eruptions have ceased.

Humus - Semidecayed plant and animal matter in soil.

Hydrologic Cycle - The giant circulatory system in which water passes through several stages: from water vapor to precipitation to surface water, and again to water vapor by means of evaporation and transpiration.

Hydrology - The study of water, especially in relation to its occurrence in streams, lakes, wells and as snow and including its discovery, uses, control, and conservation; the science that relates to the water of the earth.

Ice Age - A geological period in which ice sheets and glaciers covered large areas of the continents, reaching the sea in places and lowering the temperature of the oceans.

Ice Field - A uniform, unbroken ice-floe of great extent; a continuous sheet of ice formed when lumps of ice join up.

Ice Floe - An extensive mass of floating ice, detached from the main polar ice, whose limits of dimension are normally within sight.

Ice Sheet (Ice-Cap) - A vast mass of ice and snow that covers large land areas in the polar regions; its surface is almost flat.

Impermeable Rocks - Rocks that, being nearly non-porous, do not allow water to soak into them. This rock may be pervious owing to joints and fissures.

Impervious Rocks - Rocks that do not allow water to pass through them freely; they may be porous.

Insolation - The heat or radiant energy received from the sun by the earth and other planets.

Isostasy - The state of equilibrium existing between the highlands and the lowlands of the earth, due to the fact that the former are made of lighter rock materials than the latter.

Joint - A crack in a mass of rock that has been formed along a plane of weakness.

Kame - A mound of stratified gravel and sand that was formed by the deposition of the sediment from a stream as it ran from beneath a glacier.

Karst Region - A limestone region in which most or all of the drainage is by underground channels, the surface being dry and barren. It is characterized by sink holes and uneven topography caused by the unequal dissolution of porous underlying limestone rock.

Lacustrine - Relating to a lake or lake materials.

Landslide - The downward movement of a large mass of earth or rocks from a mountain or cliff. It is often caused by rainwater soaking into the soil and material on a steep slope; their weight is much increased, and they become more mobile. It may be caused by an earthquake or on the seacoast by the undermining action of the sea.

Lava - Molten rock that flows from fractures in the earth's outer crust out upon the earth's surface.

Leaching - The process by which water percolating downward in the soil, or moving across the surface of the soil, chemically removes soluble minerals from one place and deposits them elsewhere.

Local Relief - Amount of relief within an area in contrast to absolute altitudes above sea level.

Loess - An accumulation of fine sand transported and deposited by the wind.

Magma - Molten material that moves through the rocks of the earth's outer shell and hardens before it reaches the atmosphere.

Mantle Rock - The unconsolidated weathered material that has accumulated on the surface of the earth.

Marl - A mixture of clay and calcium carbonate, although the term is loosely applied to a wide variety of rocks and soils. Some of the marls are marine deposits while others are of fresh-water origin.

Mechanical Weathering - The weathering of rock by physical forces without chemical change.

Mesa - A flat, table-like mass, that slopes steeply on all sides. The harder top layers of rock have resisted denudation, and, being practically horizontal, have maintained a uniform surface parallel to the stratification.

Metamorphic Rock - Any rock affected by action of pressure, heat, and water, resulting in a more compact and highly crystalline condition.

Meteorology - The science that investigates the weather, in particular the physical processes that occur in the atmosphere, and the connected processes of the lithosphere and hydrosphere.

Mineral - A natural inorganic substance with fairly definite chemical composition and with distinctive physical characteristics such as crystal form, hardness, color, luster, and type of fracture.

Moraine - An irregularly shaped hill, or ridges and depressions formed by glacial deposition.

Mountain - A land mass reaching comparatively high altitude and having most of its surface in slope and of greater altitude than its surroundings.

Muskeg - A swamp or bog in an undrained or poorly drained area of alluvium or glacial till, or, more especially, in a rocky basin filled with water-saturated muck, decayed vegetal matter, and sphagnum moss incapable of sustaining much weight. The surface is commonly hummocky.

Oceanography - The study of the oceans, including the nature of the water, its movements, its temperature, its depth, the ocean bed, and the flora and fauna.

Outcrop - The portion of a rock stratum that projects above the earth's surface and is thus exposed to view.

Outwash Plain - A level area formed by deposits of minerals carried beyond the ice front of a melting glacier by running water.

Pack-Ice - Large blocks of ice, of greater extent and depth than ice-floes, that were formed on the surface of the sea when the ice-field was broken up by winds and waves, and have drifted from their original position. They are termed "close pack" if the blocks are mainly in contact, "open pack" if they are not. Most of the pack ice gradually melts and disappears in warm weather.

Pedalfer - One of the two types into which soils are sometimes classified; it is roughly equivalent to "soil of a humid region", and is rich in iron and clay. The pedalferes are divided into podzolic and lateritic soils.

Pedology - The science of the study of soils.

Peneplain - A rolling area that has experienced a long period of erosion during which mountains were generally worn down to form relatively flat terrain.

Permafrost - A thickness of soil, superficial deposit, or bedrock of variable depths beneath the surface of the earth in which below-freezing temperature has existed continuously for a long time. The term also used is perennially frozen ground. Permafrost results solely from below-freezing temperature, irrespective of the texture, degree of compaction, water content or lithologic character of the frozen materials involved.

Petrology - The study of the composition, structure, and history of the rocks forming the lithosphere or earth's crust and their mineral structure.

Physiography - The study of the physical features of the earth, their causes and their relation to one another.

Plain - An area of low relief.

Plasticity - The property of a material that enables it to undergo permanent deformation without appreciable volume change or elastic rebound, and without rupture.

Plateau - An area of relatively level land having a higher elevation than a plain and occasionally interrupted by deep valleys and areas of steep slope.

Playa - A dry-lake bed; a track of land that is temporarily filled with water and becomes a shallow muddy lake, but dries up again in hot weather.

Pleistocene - The latest epoch in the geological time scale that includes all of post-pliocene time. It is sometimes called the Ice Age.

Podzol - A type of soil that is characteristic of regions having a sub-polar climate and in a coniferous forest.

Precipitation - Water in solid or liquid form falling from the atmosphere to the earth as a result of the excessive cooling of large amounts of air.

Profile - (Soil) A section through the soil showing the different horizons, or layers, usually designated by the letters A, B, or C, that extend downwards from the surface to the parent material.

Radiation - The process by which a body emits radiant energy in the form of heat. It causes a loss of heat as cooling. Radiant energy is constantly emitted in all directions by the sun, some of this reaching the earth and converted into heat. The earth is constantly losing heat into space by radiation.

Raised Beach - A beach that has been raised by earth movement to form a narrow coastal plain; it is often bounded by inland cliffs.

Recessional Moraine - A deposit of glacial drift laid down during the retreat of a glacier.

Reef - A ridge of rocks, lying near the surface of the sea, that may be visible at low tide but is usually covered by the water.

Rift Valley - A valley lying between two relatively parallel faults.

River Terrace - A platform of land formed beside a river flowing across a plain.

Rock - One of the solid materials of which the earth's crust is mainly composed, being made of an aggregate of minerals. The many different kinds of rocks in the earth's crust are divided into three major classes: igneous, sedimentary, and metamorphic.

Salt Lake - A lake, situated usually in an arid region, in which the evaporation exceeds the amount of water entering through precipitation and inflow, so that the water becomes extremely salty.

Sand - A mass of minute particles of mineral debris that is finer than gravel but coarser than silt. It is also not as fine as dust and is not normally lifted by the winds far above the earth's surface. Its movement is controlled by obstacles in its path and it is often heaped up in mounds called dunes.

Savanna - The tropical region that borders the equatorial forest in each hemisphere and lies between the latter and the hot deserts; the natural vegetation is mainly grass with scattered trees, for there are distinct wet and dry seasons, and the lack of rainfall during the latter prevents the growth of forests except in particularly moist places.

Scarp - A relatively steep, straight slope of any height.

Scrub - A dense mass of low-growing evergreen plants, about 4 to 6 feet high, with occasional taller trees. It is usually found in regions that have insufficient rainfall or poor soil for forest growth.

Seismic Focus - The place below the earth's surface where an earthquake originates and from which the vibrations spread in all directions; it is usually several miles beneath the surface.

Seismology - The science of the study of earthquakes.

Silt - A deposit that is laid down in a river or lake, and is finer than sand but coarser than clay.

Sink Hole - A depression in the earth's surface where water has seeped down and dissolved underlying rocks or collapsed the roofs of caves.

Soil - Unconsolidated material on the earth's surface.

Soil Horizon - A distinctive layer of soil parallel to the earth's surface and having particular chemical and physical properties.

Soil Series - A group of soils having similar profiles except for the texture of the surface soil, and developed from a particular type of parent material.

Soil Structure - The arrangement of soil particles within the soil mass.

Soil Type - A term used in the classification of soils. It is the principal unit used in soil mapping as well as other soil studies.

Steppe - Short grass-type vegetation found on the humid margins of the desert regions.

Stratum - A more or less distinct layer of rock, occurring as one of a series of strata in the earth's crust. Rock strata vary in thickness from a fraction of an inch to several feet, and normally are horizontal.

Striation - A groove made by a glacier indicating the direction of the glacial movement.

Subsoil - The layer of rock particles lying below the true soil; it has less organic matter than the latter. It is less fertile than the true soil, but is penetrated to some depth by the roots of trees and plants.

Swamp - A tract of low-lying land that is saturated with moisture and usually overgrown with vegetation; it differs from a marsh in that it is not ordinarily covered with water, and from a bog in that the latter consists largely of decaying vegetation.

Talus - An accumulated heap of rock fragments derived from and lying at the base of a cliff or very steep mountain slope. The fragments may be large or small and the aggregate heap usually has a form determined by gravity and angle of rest of the material involved.

Tectonic Force - A force originating within the earth's interior, resulting from the expansion, contraction, or the transfer of molten matter, involving both the deformation of the earth's crust and the movement of molten material from one place to another.

Terminal Moraine - A deposit of glacial drift marking the farthest advance of a glacier.

Topography - A detailed description or representation of the features, both natural and artificial, of an area, that are shown on topographic maps.

Trellis Drainage - The pattern formed when major streams are arranged in relatively straight parallel lines with tributaries joining them at right angles.

Tsunami - A huge sea wave occasionally experienced along the coasts of Japan and other regions in the Pacific Ocean, caused by an earthquake taking place on the ocean bed; the wave rises to progressively greater heights as it approaches the coastline, and on a single occasion has been known to cause the deaths by drowning of thousands of people.

Tundra - A broad area of grasses, bushes, mosses, and stunted trees lying between subarctic forests and polar seas.

Valley - A long narrow depression in the earth's surface with a regular downward slope.

Volcanic Ash - Fine particles of lava that have been ejected from a volcano in eruption. The particles are coarser than those of volcanic dust.

Volcanism - The transfer of igneous or molten matter that is frequently accompanied, preceded, or followed by earth movement.

Water Table - The surface of the ground water or the surface below which the pores of a rock are saturated with water. This surface is uneven and it is also variable.

Terrain Programs in Department of Defense

I. AIR FORCE

Investigations by the Air Force Cambridge Research Laboratories (OAR) in the use of natural terrain for military operations began with studies of seismic propagation through sea ice in 1950. This led to long-term glaciological studies of ice shelves and their suitability as landing strips for aircraft (Assur, 1956; USAF AFM 86-5 Ice Airfields, 1958). Engineering studies of sea ice were culminated in Operation ICE WAY in 1961, which verified the capability of sea ice to support flight operations of the heaviest of Air Force aircraft.

A 5-year program of photogeologic identification of terrain in all environments, field investigations, site evaluations, development of techniques, and proof tests of ice-free natural land areas in Greenland was completed in 1960. This program provided detailed scientific descriptions of a number of natural soil surfaces in arctic areas that could support flight operations.

Based on these proven techniques for assessing terrain and selecting airstrip sites for use in their natural unimproved or semi-prepared condition, similar studies of dry lake bed (playa) landforms were undertaken in 1961. These involved considerations of location, bearing strength, surface roughness, seasonal conditions, site monitoring for degree of useability, site stability, and morphology.

Concurrent studies of natural terrain concerned the quantification of terrain parameters, research in the remote sensing of terrain by airborne methods, and evaluation of analogous areas. Geophysical measurements were made of typical geologic regions involving seismic, magnetic, gravimetric, and electrical resistivity measurements of surface and sub-surface structures.

Research pertaining to the landforms of global humid and tropical regions included photogeologic interpretation and analogous area studies. Field and airborne investigations of natural geothermal sources throughout the world were undertaken, primarily in Iceland and Italy.

The playa and remote sensing programs were extended to the arid regions of the world. These areas are in the Middle East, Near East, South America, and Australia.

Other agencies participating in Air Force programs have been the Army Engineers, Army Natick Laboratories, Naval Civil Engineering Laboratories, Naval Oceanographic Office, and U. S. Geological Survey. Universities and commercial organizations provided much laboratory and field assistance.

The Air Force Weapons Laboratory (AFSC) began their terrain and civil engineering research studies in 1960 to: study the effects of weapons on different soil and rock structures, develop the technology of base facilities, select sites on varied types of terrain to support facilities, and develop soil-stabilization techniques. The agency conducts studies in the evaluation of engineering properties of terrain by geophysical and remote sensing methods. Site selection studies were expanded in 1964 to include the location of suitable natural landing strips in support of operations for all types of aircraft in the Air Force inventory.

The Air Force Flight Dynamics Laboratory has been designing aircraft landing gears suitable for operating on natural or stabilized terrain and on asphalt, cement, or concrete runways. The parameters incorporated into the designs are surface roughness, bearing strength, dimensions of runways, and flight zones, wheel loading, tire size, and other related factors for all AF aircraft.

The Air Force Flight Test Center (AFSC) conducts performance tests of all aircraft on varied types of runways to determine operational characteristics and criteria for maximum capabilities and limitations. Modifications to the prototype models are made dependent upon the test results.

The Hq USAF, Directorate of Civil Engineering (AFOCE) has been responsible for the administration of the civil engineering forces and the assignment of specific operational problems for resolution to the field commands. These problems pertaining to terrain include soil stabilization, selection of sites for permanent or expedient airstrips for contingency operations, and repair or emergency construction of facilities.

The Air Force Civil Engineer Construction Operations Group (CECOG), established in 1966, is the field extension of the Hq USAF Directorate of Civil Engineering (AFOCE) as an operating subordinate unit to AFOCE. CECOG is responsible for the field organization, training, deployment, use, and logistical support of the special engineering forces to meet the requirements of the Air Force global mission. One of their major functions is the use of site selection teams for rapidly locating contingency airfields and other facilities on natural terrain to meet the expanding operational needs of the strategic, tactical, defense, and limited war forces.

2. ARMY

Corps of Engineer studies of terrain properties and vehicle mobility were initiated in the early 1930's at the Ohio River Division Laboratories and at the Waterways Experiment Station at Vicksburg, Miss. Soil trafficability studies were expanded by the Ordnance Department in 1942 and concentrated at the Waterways Experiment Station in 1945. Corollary efforts were in soil stabilization, vehicle trafficability, and aircraft landing mat research, development, and evaluation.

The Snow, Ice, and Permafrost Research Establishment was organized in 1949 to investigate the properties of polar terrain and problems of construction in an extremely cold environment. This group was combined in 1961 with the Arctic Construction and Frost Effects Laboratory (established in 1953) to form the Cold Regions Research and Engineering Laboratory (CRREL), redesignated as Terrestrial Science Center (TSC) in 1968. The Transportation Corps similarly studied operations in a polar environment, conducting vehicle and light aircraft (fixed wing and helicopter) trafficability programs since 1950.

Other Army agencies conducting theoretical and experimental investigations of terrain properties by ground and airborne methods are the Engineer Research and Development Laboratories (renamed Army Mobility Equipment Research and Development Center in 1964) and the Geodesy Intelligence and Mapping Research and Development Agency (renamed Engineer Topographic Laboratories in 1967). The Land Locomotion Laboratory at the Army Tank-Automotive Command (renamed as a Center) develops the criteria for the design of ground vehicles and conducts terrain-vehicle interaction studies for cross-country mobility. The Army Natick Laboratories was established in 1953 to develop methods for protecting military personnel and equipment in all global and regional environments. The USANL also has been responsible for climatological studies of terrain, the development

of criteria for analogous area methods, and efficient logistical use of supplies and equipment in support of military operations. Most of the efforts of the Army agencies are under the jurisdiction of the Hq U. S. Army Research Office, Corps of Engineers, and the Army Materiel Command.

3. NAVY

Terrain studies by the Navy began when the U. S. Navy Amphibious and Training Base established a beach trafficability unit in 1945 to investigate the use of beaches in operations. In 1950, the Navy delegated the responsibility of beach trafficability in DOD to the Army Engineer Waterways Experiment Station.

The Office of Naval Research performed studies of global terrain and its classification since 1950. It also initiated the long-term study of remote sensing of the environment, including terrain properties, that is mainly devoted to terrain quantification and earth science applications.

The Naval Civil Engineering Research and Evaluation Laboratory was organized in 1950 as a research unit of the Construction Battalion Corps under the Bureau of Yards and Docks. It has been concerned with installations, construction, ship-to-shore transportation, equipment, materials, and methods that are related to the engineering properties of terrain. The organization was later redesignated as Naval Civil Engineering Laboratory.

The Naval Ordnance Laboratory conducts studies of water and ice properties related to underwater ordnance and weapons. The Navy Electronics Laboratory has performed considerable work on ice properties and devised extensive instrumentation for surface and subsurface operations in a polar environment. The Naval Oceanographic Office is engaged in intensive investigations of ice surfaces, coastal shelves, reefs, barriers, marine science, sea water parameters, and submarine terrain in addition to major oceanographic studies.

Appendix B

Classification of Terrain Data

I. INTRODUCTION

The majority of terrain studies and classifications are usually qualitative or a description of the genetic origin of various landform features. A quantitative approach defines terrain parameters by a series of numerical values that offer the advantage of achieving accuracy in mapping. This approach also permits the computerization of data on all terrain parameters for an efficient determination of the effects of either an individual factor or a group of selected factors on a particular activity (see Figure 31 in report).

A semi-quantitative system combining the genetic approach with the digitization of the terrain factor values avoids over complexity yet provides more objectivity than the qualitative method in characterizing the terrain for its military significance. The terrain factor subunits of any geographic region can be identified by a series of designated digits or matrixes. Additional digits indicating any preferred range of values can be added to a matrix grouping for supplementary definition as necessary.

2. TERRAIN AND SOIL CLASSIFICATION SYSTEMS

2.1 Terrain Classification

Most terrain classification systems are qualitative and, therefore, not designed to evaluate terrain for a specific use. These qualitative systems merely describe in prose all the elements of the terrain environment, necessitating ground surveying for planning tactical operations.

2.1.1 PHYSICAL GEOGRAPHIC SYSTEM

In military geography, the regions of the world are described by the predominant physical elements of land-surface forms, as shown in Figure B-1. The major descriptive units are plains, plateaus, hills, and mountains.

2.1.2 GEOMORPHIC SYSTEM

This approach provides a genetic method for interpreting the geological structure and changing climatic processes and weathering action resulting in differential erosion of varying resistant lithology and geomorphic evolution of the landscape. The major units of classification are mountains, terraces, beaches, mesas, glacial features, etc., as listed in Table B-1.

2.1.3 REGIONAL PHYSIOGRAPHIC TERRAIN ENVIRONMENT

This method combines the physical geographic and geomorphic systems, subdividing large regions into smaller areas and predominant landform units. The terrain is classified by a synthesis of data on the geology and its processes, rocks, and stratigraphic formations, soils, vegetation, and the climate. The concept is largely intuitive, statistical, and indirect, but it can result in reliable data when employed by skilled scientifically trained analysts (Curtis, 1966).

Figure B-2 shows the extent of glaciation over a large portion of the world (Flint, 1961, p. 53), and Figures B-3 through B-8 illustrate the distribution of the other key terrain elements.

2.2 Classification of Rocks

Rock classifications are shown in Table B-2, Table B-3, and Table B-4. Generalized rock properties are listed in Table B-5.

2.2.1 CLASSIFICATION OF IGNEOUS ROCKS

In Table B-3, igneous rocks of similar chemical composition or mineral content are listed in the vertical columns; those of similar textures are listed in the horizontal columns. Classification of each variety is dependent on both texture and chemical composition.

Figure B-1. Land Surface Forms (World Distribution)

Table B-1. Summary of Landform Types, Material, and Use

<u>Landform</u>	<u>Materials</u>	<u>Use</u>
<u>Waterlaid</u>		
Flood Plains	Fine-grained and well-stratified interbedded fine silts, sand, and gravel.	Highway, airfield construction; large structures require pilings.
Filled Valleys	Coarse sands and gravels to fine silts and clays	Highways, airfield construction; drainage structure required.
Continental Alluvial Plains	Thin silt cover underlain by stratified semi-consolidated materials of all textures	Highways, airfield, and building construction; drainage for dam sites required to prevent leakage.
Alluvial Fans and Related Forms		Highways, airfield, and building construction; drainage structure required; water supply.
Talus Cones	Rock fragments	
Alluvial Cones	Medium size rock fragments	
Alluvial Fans	Silt, clays, sand, gravel	
Delta Fan	Silt, clays, sand, gravel	
	Unconsolidated sands and small gravel with pockets of silt and clay	
Deltas	Silt, clays, sand, and gravel in stratified, cross-bedded, thick deposits of unconsolidated deposits	Source of construction materials.
Dry Lakebeds (Playas)	Unconsolidated fine sands, clays, silts, and salts	Roads, airfields, and buildings; foundation support for structures required.
Beach Ridges	Sand and gravel	Road, railroad lines; source of construction material.
Coastal Plains	Interbedded clays, silts, and sands in unconsolidated deposits	Road, railroad lines on undissected areas; landslide conditions; drainage controls required.
Tidal Flats	Silt, clay, and sand	Roads require stabilization; source of construction materials.
Marsh and Swamp	Peat, muck, silt	Temporary roads must be stabilized.

Table B-1. Summary of Landform Types, Material, and Use (Cont'd)

<u>Landform</u>	<u>Materials</u>	<u>Use</u>
<u>Glacial</u>		
Eskers	Sand, gravel, and sand	Roads, railroad lines; source of construction material.
Kames	Fine sand, silt, and gravel	Source of construction material.
Outwash Plains	Stratified sand and gravel	Source of construction material and foundations with stabilization.
Terraces	Sand, gravel, clays, silt	Foundations for structures require stabilization; source of construction materials.
Lakebeds		Foundations for structures require stabilization; drainage controls needed.
Delta Deposits	Coarse sand and gravel	
Near-Shore Deposits	Coarse silt and sand	
Deep-Water Deposits	Silts and clays	
Till Plains	Silt, clay, gravel	Foundation for structures require stabilization; drainage controls needed.
Moraines	Silt, clay, sand, boulders	Source of construction material; drainage controls needed; foundation for structures require stabilization.
Drumlins	Sand, clay, and gravel	Source of construction material.
<u>Windlaid</u>		
Sand Dunes	Sand	Source of sand for construction; foundation for structures requires stabilization.
Loess	Silt	Foundation for structures requires stabilization.

GLACIATED AREAS OF THE WORLD

■ AREAS OF FORMER GLACIATION ■ AREAS OF PRESENT GLACIATION

Figure B-5. Metamorphic Rocks (World Distribution)

Figure B-6. Soil (World Distribution)

Figure B-7. Vegetation (World Distribution)

Figure B-8. Climate (World Distribution)

Table B-2. Igneous Rocks

Composition			
Texture	Acidic Rocks (more than 50 percent silica)		Basic Rocks (less than 50 percent silica)
	Light-colored minerals, chiefly feldspar, pre- dominate		Dark-colored minerals predominate
	Abundant quartz	Little or no quartz	Abundant amphibole pyroxene, and plagio- clase feldspar
Coarse-grained (mineral crystals easily visible to naked eye).	Granite	Diorite	Gabbro
Fine-grained (mineral crystals generally in- visible to naked eye).	Rhyolite	Andesite*	Basalt*
Glassy	Obsidian, pitch- stone, pumice		

* Sometimes called traprock.

2.2.2 CLASSIFICATION OF SEDIMENTARY ROCKS

Sedimentary rocks (Table B-3) are classified as clastic, pyroclastic, chemical, or organic, based upon the mode of origin of the sediment from which they are derived. The clastic rocks commonly show separate grains. The chemical precipitates and evaporates, on the other hand, either have interlocking crystals or are in earthy masses. The organically formed rocks commonly contain easily recognized animal and plant remains, such as shells, bones, stems, or leaves.

2.2.3 CLASSIFICATION OF COMMON METAMORPHIC ROCKS

Metamorphic rocks (Table B-4), on the basis of their primary structure, are readily divided into two descriptive groups: the foliates and non-foliate. The foliated metamorphic rocks display a pronounced primary structure, as they have a banded appearance from the differential pressures to which they have been subjected. The nonfoliated or massive metamorphic rocks exhibit no primary structural features. These structural differences are used as the basis for the simplified classification of the common metamorphic rocks.

Table B-3. Sedimentary Rocks

Type	Sediment	Rock
Clastic or fragmental	Coarse (gravel) Medium (sand) Fines (silt and clay)	Conglomerate Sandstone Siltstone and shale
Pyroclastic	Coarse (cinder) Fine (ash)	Agglomerate Tuff
Chemical precipitates and evaporites	Calcium carbonate (CaCO_3) Calcium magnesium carbonate ($\text{Ca}(\text{Mg, Fe}) (\text{CO}_3)$) Silicon dioxide (SiO_2) Calcium sulphate ($\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$) (CaSO_4) Sodium Chloride (NaCl)	Limestone Dolomite Chert Gypsum anhydrite
Organic	Calcium carbonate (animal remains) Carbon (plant remains)	Rock salt Coquina, some coral rock, and chalk Coal

Table B-4. Metamorphic Rocks

FOLIATED		
Texture	Rock	Characteristics
Coarse-grained	Gneiss	Streaked or banded; imperfectly foliated
Medium-grained	Schist	Well-foliated; splits easily; generally rich in mica
Fine-grained	Slate	Splits readily into smooth sheets
NONFOLIATED AND MASSIVE		
Mineral Content	Rock	Characteristics
Chiefly quartz	Quartzite	Hard and brittle
Chiefly calcite (or dolomite)	Marble	
Chiefly hydrous magnesium silicate	Some types of serpentine	Fairly soft; green

Table B-5. Generalized Rock Properties

Rock Type	RATINGS OF WORKING CHARACTERISTICS

Modified from von Balow (Ref. 22)

Abrasive-ness (as it affects excavation tools and equipment):

- A. Extreme
- B. Severe
- C. Moderate
- D. Slight
- E. Nominal or none

Tools and procedures required to excavate rock:

- a. Spade and shovel
- b. Pick and shovel
- c. Pick, crowbar, and wedge
- d. Repeated drilling and blasting
- e. Almost continuous drilling and blasting

All other properties:

- 1. Excellent
- 2. Good
- 3. Adequate or fair
- 4. Poor or usable only in emergencies
- 5. Inadequate, unsuitable or absent

2.3 Soil Classification

Most soil classification systems are based on grain size analysis, with arbitrary limits of grain sizes set for different soil groups. These major soil categories are gravels and sands (coarse-grained soils), silts and clays (fine-grained), and organics. The percentage of each particular type (gravel, sand, silt, or clay) in a composite soil determines the classification of the soil. Some classification systems describe the identified soil constituents, and others determine the engineering properties of a soil.

Of the eight or more methods developed for classifying soils, three systems — Unified Soil Classification System, Agricultural Soil Classification System, and Geologic Soil Classification System — are the most commonly used.

2.3.1 UNIFIED SOIL CLASSIFICATION SYSTEM

This system, known as the USCS, classifies the physical properties of soil for engineering purposes (see Tables B-6, B-7, and Figure B-8). It lists eight groups of coarse-grained soils, six groups of fine-grained soils, and one group of organic soils.

Identification and classification are based upon grain size, mechanical analysis, plastic limit tests, and other physical properties.

2.3.2 AGRICULTURAL SOIL CLASSIFICATION SYSTEM

This system, known as USDA, classifies surface soils for agricultural purposes (Figure B-9). Based on physical properties and specific percentages of gravel, sand, silt, and clay in a composite soil, the potential agricultural productivity of a soil can be determined. The soil properties also reflect the influence of geologic processes, age, climate, vegetation, and topographic features. Figure 2 in the report lists the gradation limits of soil for use with Figure B-9.

2.3.3 GEOLOGIC SOIL CLASSIFICATION SYSTEM

This system is based upon the geologic origin of soils. The major divisions of residual and transported soils by landform features are glacial, fluvial (stream-laid), eolian (wind blown), lacustrine (water), littoral (shore), and volcanic.

The Wentworth Scale is used to classify a soil or rock by grain size gradation from boulders to fine-grained soils, as listed in Figure 2 in the report (Leet and Judson, 1965, p. 98).

Figure B-9. USDA Soil Textural Classification

2.3.4 CORRELATION OF SOIL CLASSIFICATION SYSTEMS

With certain limitations, laboratory analysis of soil samples has shown that a general correlation exists between the USCS and USDA soil types (U. S. Army C.E.WES, TM 3-240, 16th Supplement). Of 1176 samples classified, many categories of the USDA Agricultural Soil Classification System can be correlated with the soil groups of the Unified Soil Classification System. The correlations range from 41 to 100 percent, the average being about 60 percent. See Table B-8. The grain size and soil groups of the USDA, USCS, and Wentworth systems are shown in Figure 2 in the report to be in close agreement.

Table B-8. Frequency of USDA Types Occurring as USCS Soil Types

		USCS Soil Type																Total %		n
		Coarse-Grained Soils With Fines						Fine-Grained Soils				Organic Soils								
		GW	GP	GM-W	GM	GM-FC	GC	SW	CL-ML	MH	CL	CH	OL	OH	Pt					
USDA Soil Type	Sand, Sols	S			4	1												100		
		n			21	1												46		
		L				1												100		
		n				1												57		
		CL†				1				4				2	2			100		
		n	1									1		5	4			207		
	CL	CL				11		2			1							100		
		n						1			1							29		
		CL									60							100		
		n																2		
	Clayey, Silty, and Heavy Soils	CL							11			1		3		4		100		
		n			1					1						1		161		
		CL							6	10	3	1		2	2	2		100		
		n							172	47	16	21				10		441		
		CL							1									100		
		n							1									11		
		CL									1		15			1		100		
		n									1		39			1		40		
	Organic Soils	SiCL							1	1	1	1	27			3		100		
		n							1	1	1	1	27			2		34		
		SiCL									24	1						100		
		n							1				1					21		
	Organic Soils	C							3		10	13	1					100		
		n							3		10	13	1					27		
	Organic Soils	Pt															1	100		
		n															1	1		
Total samples																			117	

n = Number of samples.

* = Less than 1%.

† = Prefixed with the term gravelly, silty, or stony for GM or GC soil types.

		Sample Interpretation
SiL	CL	45% of all SiL samples were CL. The sample indicates that a greater number of SiL samples occurred as CL than as any other USCS type. 215 samples were classified as SiL and CL.
	215	

3. BEARING STRENGTH OF TERRAIN AND SOIL.

An index of trafficability for most ground vehicles is the wet season characteristics of soil and generally trafficable vegetation as shown in Table B-9. Most dry soils and certain saturated fine-grained soils have a relatively high resistance to penetration, while many physical properties contribute to the bearing strength of a soil.

The primary determinant of bearing strength is the nature of the surface materials — its density, grain size and shape, moisture content, and vegetation — which are measured in standard engineering terms of the California Bearing Ratio applied to soil and rock strength. Moisture affects the strength of some soils severely (Figure B-10).

The distribution of soil-strength regions in the world (Figure B-11) show five qualitative divisions for trafficability conditions based on an interpretation and evaluation of Figures B-1, B-5, B-6, B-7, B-9, and B-10. The divisions are: (1) soft ground most of the time, (2) soft ground and firm ground alternating all year, (3) seasonality of soft and firm ground, (4) season of firm ground and season of alternating firm and soft ground, and (5) firm ground most of the time. About 78 percent of the land area of the world has a firm soil with a Rating Cone Index exceeding 60; 17 percent has a soft soil with a RCI of from 25 to 60; and 5 percent has a very soft soil with a RCI of less than 25.

3.1 California Bearing Ratio (CBR)

The California Bearing Ratio is the most reliable engineering test for measuring the shearing and traction resistance of a soil under controlled conditions of density and moisture (AFM 88-52, AFM 88-51, TM 5-541). Refer to Appendix C of this report for further information.

3.2 Terrain and Soil as Foundation Materials

For guidance in the design of major facilities and structures, an estimation of the maximum allowable loading values, in tons per square foot, is shown in Table B-10 for all types of rocks and soils (Aviation Egr. Force, 1956). These values vary from 1 ton PSF to over 40, but do not apply if the foundation is underlain by a weaker material. Controlled laboratory and field tests of representative samples obtained from the proposed site are always recommended prior to construction (AFM 88-52, p. 286).

Table B-9. Trafficability Characteristics of USCS Soils in Wet Season

Class	Soils	USCS Soil Type	Probable CI Range	Probable RI Range	Probable RCI Range	Slipperiness Effects	Stickiness Effects	Comments
A	Coarse-grained, cohesionless sand and gravels	GW, GP SW, SP	80 to 300	1	80 to 300	Slight to none	None	Will support continuous traffic of military vehicle tracks or with high tires. Moist sand dry sand only fair. Wheeled vehicles with standard tires may be immobilized in dry sands
E	Inorganic clays of high plasticity, fat clays	CH	55 to 165	0.75 to 1.35	65 to 140	Severe to slight	Severe to slight	Usually will support more than 50 passes of military vehicles. Going will be difficult at times
C	Clayey gravels, gravel-sand-clay mixture	GC	85 to 175	0.45 to 0.75	45 to 125	Severe to slight	Moderate to slight	Often will not support 40 to 50 passes of military vehicles, but usually will support unlimited traffic. Going will be difficult in most cases
	Clayey sand, sand-clay mixtures	SC						
	Gravelly clays, sandy clays, inorganic clays of low to medium plasticity, lean clays, silty clays	CL						
D	Silty Gravels, gravel-sand-silt mixtures	GM	85 to 180	0.25 to 0.85	25 to 120	Moderate to slight	Slight	Usually will not support 40 to 50 passes of military vehicles. Often will not permit even a single pass. Going will be difficult in most cases
	Silty sands, sand-silt mixtures	SM						
	Inorganic silts and very fine sands, rock flour, silty or clayey fine sands or clayey silts with slight plasticity	ML and CL-ML						
	Inorganic silts, micaceous or diatomaceous fine sandy or silty soils, elastic silts	MH						
	Organic silts and organic silty clays of low plasticity	OL						
	Organic clays of medium to high plasticity, organic silts	OH						
E	Peats and mucks	Pt	10 to 100	0.25 to 0.65	10 to 85	Slight to none	Moderate to slight	Often will not permit even a single pass. Going will be difficult to impossible

Note: Taken from Trafficability of Soils, A Summary of Trafficability Studies Through 1955, TM No. 3-240, 14th Supplement, December 1956

Figure B-10. Variation of Soil Strengths With Moisture Content and Correlation of Cone Index With California Bearing Ratio

Figure B-11. Soil Strength Regions (World Distribution)

Table B-10. Allowable Pressures for the Design of Shallow Foundations

	Maximum allowable pressure, tons per square foot
Hard, sound rock	40+
Soft rock	8-10
Hardpan overlying rock	10-12
Compact gravel and boulder-gravel deposits; very compact sandy gravel	10
Loose gravel and sandy gravel; compact sand and gravelly sand; very compact inorganic sand-silt soils	5-6
Hard, dry, consolidated clay	5
Loose coarse to medium sand; medium compact fine sand	4
Compact sand-clay soils	3
Loose fine sand; medium compact inorganic sand-silt soils	2
Firm or stiff clay	1.5-2
Loose saturated sand-clay soils; medium soft clay	1

Note. Values are not applicable if foundation soil is underlain by a weaker soil. Use of the tabular values for the design of shallow foundations of major structures is not recommended unless their use is justified by experience or additional investigation.

Appendix C

Data Acquisition and Representative Applied Processing

1. INTRODUCTION

Terrain data acquired by either the contact, non-contact, or indirect method can be digitized conveniently to characterize the factor groups and their subclasses. This permits their amenability to computer system programming (processing, storage, retrieval, analysis, and presentation phases). In data processing terms, the application (that is, the specifications of proposed use of the terrain being evaluated) and the terrain factors (designators) constitute the input; the result of their interaction is the evaluation model; and the measure of predicted performance under a given set of environmental conditions is the output. The description of the tests, nomenclature of equipment, and computer models of specific cases are beyond the scope of this report. The computer approach is applicable to a broad spectrum of military uses.

2. CONTACT METHOD

The field measurement of all terrain factors and their subclasses is done with standard testing and sampling equipment and by procedures that are described in detail in the literature. Some new equipment used is described in Section 5 below.

With the contact method, each critical value of the specified terrain factor and its subclass at the surface and subsurface is measured and mapped precisely for total data quantification. Such data can be used directly for computerized storage or applied to the model of the required use. The data also can serve as ground controls and clues to the non-contact imagery.

3. NON-CONTACT METHOD

Remote sensing of the terrain environment yields largely qualitative but some semi-quantitative information. Figure 10 in the report indicates the type of sensors used and the extensive instrumentation necessary for acquiring and interpreting the data. These sensors are aerial photography in the ultraviolet, visible, and infrared; radar; radio waves; and instrumentation in air-drop devices. The references on remote sensing are numerous; the reader is referred to a selected list in the bibliography under a special heading, Remote Sensing Publications.

4. INDIRECT METHOD

The indirect method of terrain-data acquisition is often employed to estimate the critical terrain factor class values. Highly trained individuals can infer, evaluate, and predict terrain characteristics and expected performance of a military activity through analysis of data acquired by this method.

This method utilizes standard photographic and photogrammetric devices, data obtained from the contact and non-contact methods, library source data, and the skills of regional, scientific, and technical specialists.

5. DEVICES FOR MEASURING BEARING STRENGTH OF TERRAIN PROFILE

The terrain factor subclass affecting the trafficability and load-bearing capacity of a soil is its shear strength. Although vegetation and its root structure, interbedded rock and gravel, and other terrain properties influence its strength, the measured shearing resistance of a soil mainly indicates its degree of ability to support military air and ground operations, such as aircraft and vehicular trafficability.

5.1 Cone Penetrometers

Several types of penetrometers have been developed to measure the soil shearing and traction resistance for the trafficability evaluation of unsurfaced areas (TM 3-240, Supp. 1; USA WES Landing Strip Evaluation, 1952). In Figure C-1, penetrometer measurements of fine-grained soils, in units of cone index, are conservatively correlated with CBR criteria of specific calibrated soil types.

Vehicle and aircraft trafficability and other requirements for composite or single-soil load-bearing strengths are based upon direct CBR or CBR-equivalent values (Figure C-2). Further refinement of CBR-equivalent correlations of penetrometer index values for different soils will narrow the deviation from directly measured CBR data (Molineux, 1955; USA WES Misc. Paper 4-101).

Variation of soil strength with moisture content and correlations of cone index of selected classified soil types with CBR-equivalents are illustrated in Figures B-10 and C-1. The cone index shown in the curves refers to the Army Engineer proving ring penetrometer criteria, unless otherwise designated as the tension spring model.

5.1.1 SHEAR STRENGTH CONE INDEX

Any air-drop or ground cone penetrometer measures the cone index, and this measurement is correlated with the California Bearing Ratio (CBR) by soil type, as classified by the USCS System, to obtain CBR-equivalent units.

Basically, a penetrometer is a bearing-strength measuring device consisting of a 30-deg circular cone mounted on the end of a steel shaft; the cone normally has a base end area of 0.5 sq in. The force required for the cone to penetrate the ground surface is indicated on a dial or on an engraved scale. Generally, air-drop models are previously calibrated to shear a pin of known cone index. The use and design of the penetrometer (proving ring) and related test equipment, including the manual, linear, coiled-tension-spring model (150- and 300-lb models) are completely described in AFM 88-51, p. 93. The proving ring model has a dial ranging from 0 to 300 (Figure C-3). The value 300 occurs under a force of 150 lb. The spring model is read directly in pounds of force, with a maximum limit of 300 lb (Figure C-4).

Air-drop devices are treated in Chapter III, Remote Sensing.

5.1.2 AUTOMATIC RECORDING CONE PENETROMETER

An automatic recording model based on the original 300-lb spring-load design model was developed by Air Force Cambridge Research Laboratories and is

Figure C-1. Relation of Cone Index to California Bearing Ratio, Unconfined Compressive Strength, and North Dakota Cone Bearing Strength

Figure C-2. California Bearing Ratio Required for Operation of Aircraft on Unsurfaced Soils by Wheel Load, Tire Pressure, and Traffic in Coverages

Figure C-3. Proving Ring Manual Cone Penetrometer

Figure C-4. AFCRL Tension Spring Manual Cone Penetrometer

shown in Figure C-5. It incorporates all the features of the AFCRL manual air-field penetrometer, in addition to having the capability of recording and providing strength-thickness information automatically and immediately. The most important improvement is that the maximum soil load-bearing-strength measurement has been extended to a CBR (equivalent) of over 70. An added feature is that this instrument can be operated in darkness.

This model retains the standard 30-deg cone tip mounted on a 20-in.-long, 7/16-in. shaft. A spring-loaded chain-drive action is proportional to the load applied to the cone. A maximum of 600 lb is designed for the spring load. Dual cranker levers drive the rod-mounted cone into the soil. Data are rapidly obtained as a permanent record. The instrument can be operated by non-professional personnel.

Figure C-5. AFCRL Automatic Recording Cone Penetrometer (600 lb Model)

6. MATRIX DESIGNATOR METHOD

A class value coding system of digitized terrain parameters (matrix groups) can be used to describe an area of interest for military operations. Within each matrix group, the associated parameters are sub-divided into classes to designate the characteristic features in terms of the primary and secondary parameter groups, depending upon the application. Matrix coding can be increased to characterize complex terrain conditions more accurately. The system permits the flexibility for extending parameter limits, modifying categories, and adding new parameters.

6.1 Matrix Composition

Each matrix group is composed of several classes selected to meet the requirements for terrain information. A single terrain factor is divided into a number of matrix class ranges with an assigned class designator in an arrangement of sequential coding (Bredhal and Kiefer, 1957, p. 40).

6.2 Description of Natural Unprepared Landing Surface by Matrix Format

The system for describing landing areas establishes a minimum of five matrix groups, each of which is described by a class-designator code for the selected related factors. These groups and subclasses, as summarized in Tables C-1 to C-7, are suitable for describing any area in a global terrain environment.

Table C-1. Terrain Matrix Classes of Landing Areas

Matrix	Parameter Group	Parameter Subclass	Class Designator Code	Table of Class Designators
Group I (3 Digits)	Landing Area	Length (Ft) Width Slope (Deg) Length Slope (Deg)	1st & 2nd Digits 3rd Digit 4th Digit	Table C-2

6.2.1 TERRAIN MATRIX DESIGNATOR

The codes of the factors and subclasses by matrix group form the respective matrix group designators. The Simple Terrain Matrix Designator, comprised of the five matrix groups, as illustrated in Figure C-6, indicates the following assumed landing area described in minimum detail as 0311-112-145-0904-035:

<u>Matrix Group I</u>	(Matrix Group Designator: <u>0311</u>)
Length: 500-6500 ft	(1st and 2nd Digits: 03XX)
Width Slope: 0-2 deg	(3rd Digit: XXIX)
Length Slope: 2-4 deg	(4th Digit: XXXI)
<u>Matrix Group II</u>	(Matrix Group Designator: <u>112</u>)
Undulation Height: 3-6 in.	(1st Digit: IXX)
Undulation Slope: 2-4 deg	(2nd Digit: X4X)
Undulation Spacing: 50-100 ft	(3rd Digit: XX2)
<u>Matrix Group III</u>	(Matrix Group Designator: <u>145</u>)
Obstacle Height: 3-5 in.	(1st Digit: IXX)
Obstacle Spacing: 25-50 ft	(2nd Digit: X4X)
Obstacle Type: Loose Stones	(3rd Digit: XXS)
<u>Matrix Group IV</u>	(Matrix Group Designator: <u>0904</u>)
Soil Type: Inorganic Clay, Type Cl.	(1st and 2nd Digits: 09XX)
Soil Strength: CBR 9-10	(3rd and 4th Digits: XX04)
<u>Matrix Group V</u>	(Matrix Group Designator: <u>035</u>)
Type of Aircraft: C-130	(1st and 2nd Digits: 03X)
Trafficability: Operational	(3rd Digit: XX5)

Figure C-6. Simple Terrain Matrix Designator

6.2.1.1 Complex Terrain Matrix Designator

Varying conditions cause the designator to become more complex as additional information is incorporated into the description. Figure C-7 is an example of a more detailed designator that could be applied to the additional data listed below:

$$\begin{array}{r} 0311 \\ \hline 250 \end{array} - \begin{array}{r} 112 \\ 232M \\ \hline -598E \\ 3 \end{array} \quad \begin{array}{r} 14S \\ 06R \\ 47B \end{array} - \begin{array}{r} 0904 \\ \hline 10 \end{array} - \begin{array}{r} 035 \\ \hline 65 \end{array}$$

7. MATRIX DESCRIPTION OF REPRESENTATIVE TERRAIN

Two small areas of terrain in Hart County, Kentucky, were selected as examples for the application of the proposed method of quantifying the trafficability characteristics at each location. The first case example described with the aid of an aerial stereophotographic view by a Simple Terrain Designator (0921 705L 94T 0907 035), depicts conditions suitable for landing a C-130 aircraft or smaller. A secondary Matrix V class designator may be added for equivalent vehicular traffic or other uses (Figure C-8).

Figure C-7. Complex Terrain Matrix Designer

The second case example, also shown in a similar stereophotographic view, is a Complex Terrain Designator $\frac{0902}{368}$ 717 WC 61T 0906 $\frac{035}{65}$ that describes in more detail the capability of the terrain to support particular categories of aircraft and vehicular traffic (Figure C-9). Topographic cross-section profiles are inserted below each stereopair for ease in visualizing the microrelief along the cross profiles in both areas.

Table C-8 tabulates the many related important trafficability characteristics of Hart County, Kentucky, which includes Areas A and B. They are bearing strength, surface features, vegetation, and hydrology. Climate and weather of the area were classified under the Köppen System; they are: Cfa, which denotes warm temperature climate (C), sufficient precipitation in all months (f), and warmest month mean over 71.6°F or 22°C (a).

The trafficability units of Area A (see Table C-8) are largely 1'a followed by 4' and 2'b in progressively minor occurrence. The units of Area B are 1'a, 1'b, and 2'a in a similar order.

* The RCI given is the minimum probable value during the wet season; correlate with California Bearing Ratio equivalent. These features must, in general, include slopes greater than 1 ft in height and steeper than 60%. The scale of value is as follows:

- a: Numerous.
b: Common.
c: Present, but not common.
d: Rare.
e: Absent.

† Mean distance in miles between gullies, ditches, or cut and fill banks along a random straight line.

†† The scale of values for tree density is:

- A: Dense; passable, but path tortuous.
B: Moderately dense; passable, but path length substantially extended.
C: Patches and rows; path length slightly extended.
D: Rare or absent; no appreciable effect on path length.

‡ The scale of values for shrub density is:

- A: Dense; visibility seriously inhibited; path selection difficult.
B: Moderately dense; visibility somewhat inhibited; path selection not seriously inhibited.
C: Rare or absent; visibility not appreciably affected; path selection easy.

‡‡ The scale of values for hydrographic features is:

- 1: Surface water absent.
2: Small ponds, easily bypassed.
3: Unfordable water barrier subdivides region.
Curbs, terraces, walls, etc.

8. MATRIX DATA FROM LIBRARY SYSTEM OF ANNOTATED REMOTE SENSING IMAGERY

A system of recording, indexing, and storing information for rapid and efficient retrieval by an analyst is most advantageous in the development of a complete matrix designator of terrain.

Basic recording techniques can serve other military applications such as site selection, if reliable data are stored and properly indexed. The data storage could be on punched or marked cards or in folders, handbooks, or folios.

The indexing of a terrain environment would include all the terrain factors and related information by location, subject, photography, maps, reports, and other sources of data related to the specific problem. Refer to the report, "Handbook for Producing a Folder for a Library of Annotated Aerial Photographs", by H. T. Leibowitz, University of Oxford, December 1966 (AD 814 934) for comprehensive recording procedures that can provide other types of useful data to supplement a terrain matrix designator.

APPENDIX D

Optimum Remote Sensing System

The designation of an optimum remote sensing system for determining, measuring, and monitoring natural terrain properties and conditions depends on its proposed applications and on available resources for system development. Many surveys and feasibility studies have been made, and tabulations prepared, regarding the capabilities of various sensors, either singly or grouped, to obtain the necessary data. In actual usage problems of weight and volume, power requirements, mutual interference, and output format must be carefully considered.

It is generally recognized that photography is the most useful sensor system, as its output is most familiar to the human senses and its interpretation has been most highly developed. Extending to either side of the narrow visible and photographic wavelengths of the electromagnetic spectrum are ultraviolet and infrared, both of which can be used to record valuable data. The existence of "atmospheric windows", permitting the transmission and recording of longer wavelength infrared energy, makes the use of infrared scanners very profitable.

Further into the microwave region of the spectrum, the use of passive microwave radiometry and active or passive radar (both imaging and non-imaging) becomes of value. Radar imagery can reveal much information regarding geologic formations and both surface and sub-surface earth properties, and its interpretation is fairly well developed in the geoscience community. Radar altimeters in particular are of value in studies of the regional relief or topography of the earth's surface.

At the opposite end of the spectrum, gamma-ray sensing is used in mineral exploration and shows much promise for determination of soil type and moisture content. Airborne use of this technique requires low-level surveys and quite large arrays of detectors.

The natural force fields of gravity and magnetism also offer clues as to the existence and extent of geologic materials and subsurface conditions. Airborne use of these techniques is quite standard, and data interpretation is well developed.

Droppable sensors for determining soil properties such as strength are well developed, and the Sandia Corporation's use of deep-penetrating projectiles is an advanced technique worthy of use in an optimum sensing system.

The recent development of lasers has a most useful application in very-high-resolution airborne profile recorders for measuring microrelief within 12 in. of accuracy. Studies of laser reflection "signatures" on rock and soil material are underway, which ultimately should permit material identification and discrimination.

Figure D-1, prepared for NASA purposes, presents an overall view of sensors that have varied uses in the earth sciences. The resolution of sensors at spacecraft altitudes is necessarily less than at aircraft altitudes, but the sensors can obtain some useful geophysical data.

In general, an optimum system should contain a metric or mapping camera using standard black and white film to obtain an overall view of the terrain being surveyed; a panoramic camera to extend the view of the area to include surrounding terrain; a multispectral camera system to exploit the spectral reflectance signatures of terrain material; and other mapping cameras simultaneously collecting data on color and infrared films. An additional camera using ultraviolet sensitive film would be a valuable additional source of data for experimental studies. Spectrally filtered photometers bore-sighted with the cameras would also be desirable.

Three optical-mechanical scanners are considered necessary in an optimum system. Two of these should operate in the 3 to 5 μ and 8 to 14 μ infrared regions, respectively, and the other should provide multi-wavelength scanning throughout the visible spectrum.

A high-resolution, side-looking, imaging radar, a radar scatterometer, (Moore, 1966) a long-wavelength radar, a laser altimeter, and an all sweeping-frequency radar should provide both surface and sub-surface data.

A passive microwave imager with a multi-frequency microwave radiometer having dual-polarization capability would provide additional data.

An airborne magnetometer and airborne gravimeter would acquire useful supplementary information on the existence of geologic conditions revealed in the force field anomalies. Airborne electromagnetic sensors would detect changes in conductivity or the dielectric constant associated with variations of sub-surface formations.

An array of gamma-ray detectors and scintillometers is needed to enhance the measurement of soil types and their extent and to provide needed data on mineral deposits.

A capability to airdrop contact sensors should be part of an airborne system, as well as an extensive telemetry recording capability to obtain supplementary "ground truth" data.

Inherent in all the above discussion is the necessity for precise navigation of the aircraft carrying the remote sensing system, the existence of suitable viewfinders and driftmeters for photographic positioning control, and an overall time-marking system for precisely coordinating all navigation data, sensor outputs, and events. On-board processing of film, for at least test strips, is seen as valuable but not mandatory.

The various sensors have widely diverse output formats, such as film recording, strip charts, tape records, and telemetry voltages. Digitizing as much as possible of the output format and recording the signal on multi-channel tape recorders is seen as a feasible present approach. In the future, the development of automated, real-time, photo-processing and recording of data by flying-spot scanners and densitometers should enable the consolidation of all sensor outputs and a computer correlation with known pattern recognition techniques into near-real-time presentation. A digitized total "terrain data bank" stored in a ground computer station could provide quantitative values of terrain factors such as type, slope, moisture, temperature, etc., for any required application from such digitized interpretive processes shown in Figure D-2 and in Figure 31 of the report.

13. ABSTRACT A survey of the state-of-the-art in the evaluation of natural terrain by earth-science techniques and measurement systems is presented in response to a need that existed for many years. This report considers the terrain as an envelope of the environment and all related parameters that are basic in an evaluation for relevant military applications such as unimproved landing areas, trafficability, site selection for operational facilities, terrain reconnaissance and surveillance, and target detection within a marked terrain complex. Methods of terrain-data acquisition, analysis, and evaluation and their limitations are reviewed. The status of research and development, specifying the gaps in technology, is summarized with accompanying conclusions. The report forecasts the requirement for an automated terrain-data acquisition, storage, and display system. Recommendations are suggested for further investigation to advance technology that will provide quantitative terrain factor values. A simplified matrix method of digitizing terrain data is described in the appendix as a necessary intermediate step to the computerization of pertinent data. Information pertaining to the classification of terrain data, field devices to measure bearing strength, and a visualized optimum remote sensing system is also given in the appendix. A glossary and a comprehensive bibliography are included.

Terrain Analysis

Preface

SCOPE

Terrain analysis, an integral part of the intelligence preparation of the battlefield (IPB), plays a key role in any military operation. During peacetime, terrain analysts build extensive data bases for each potential area of operations. They provide a base for all intelligence operations, tactical decisions, and tactical operations. They also support the planning and execution of most other battlefield functions. Because terrain features continually undergo change on the earth's surface, data bases must be continuously revised and updated.

PURPOSE

This field manual prescribes basic doctrine and is intended to serve as a primary source of the most current available information on terrain analysis procedures for all personnel who plan, supervise, and conduct terrain analysis. The manual discusses the impact of the terrain and the weather on operations.

USER INFORMATION

The proponent of this publication is the US Army Engineer School. Submit changes for improving the publication on DA Form 2028 (Recommended Changes to Publications and Blank Forms) to Commandant, Directorate of Training and Doctrine, US Army Engineer School, ATTN: ATSE-TDM-P, Ft. Leonard Wood, MO 65473-6500.

Approved for public release; distribution is unlimited.

Unless otherwise stated, whenever the masculine gender is used, both men and women are included.

*This publication supersedes FM 21-33, 15 May 1978, and FM 30-10, 27 March 1972.

DISTRIBUTION:

Active Army, USAR, and ARNG: To be distributed in accordance with DA Form 12-11E, requirements for FM 5-33, Terrain Analysis (Qty rqr block no. 4329).

Natural Terrain

Chapter 1

SURFACE CONFIGURATION

Maneuver commanders must have accurate intelligence on the surface configuration of the terrain. Ravines, embankments, ditches, plowed fields, boulder fields, and rice-field dikes are typical surface configurations that influence military activities. Elevations, depressions, slope, landform type, and surface roughness are some of the terrain factors that affect movement of troops, equipment, and material.

Landforms

Landforms are the physical expression of the land surface. The principal groups of landforms are plains or plateaus, hills, and mountains. Within each of these groups are surface features of a smaller size, such as flat lowlands and valleys. Each type results from the interaction of earth processes in a region with given climate and rock conditions. A complete study of a landform includes determination of its size, shape, arrangement, surface configuration, and relationship to the surrounding area.

Relief

Local relief is the difference in elevation between the points in a given area. The elevations or irregularities of a land surface are represented on graphics by contours, hypsometric tints, shading, spot elevations, and hachures.

Slope or Gradient

Slope can be expressed as the slope ratio or gradient, the angle of slope, or the percent of slope. The slope ratio is a fraction in which the vertical distance is the numerator and the horizontal distance is the denominator. The angle of slope in degrees is the angular difference the inclined surface makes with the horizontal plane. The tangent of the slope angle is determined by dividing the vertical distance by the horizontal distance between the highest and lowest elevations of the inclined

surface. The actual angle is found by using trigonometric tables. The percent of slope is the number of meters of elevation per 100 meters of horizontal distance. Slope information that is available to the analyst in degrees or in ratio values may be converted to percent of slope by using a nomogram.

VEGETATION FEATURES

Plant cover can affect military tactics, decisions, and operations. Perhaps the most important is concealment. To make reliable evaluations when preparing vegetation overlays, analysts must collect data on the potential effects of vegetation on vehicular and foot movement, rover and concealment, observation, airdrops, and construction materials.

Types

The types of vegetation in an area can give an indication of the climatic conditions, soil, drainage, and water supply. Terrain analysts are interested in trees, scrubs and shrubs, grasses, and crops.

On military maps, any perennial vegetation high enough to conceal troops or thick enough to be a serious obstacle to free passage is classified as woods or brushwood. Although trees provide good cover and concealment, they can present problems to movement of armor and wheeled vehicles. Woods also slow down the movement of dismounted troops. Individual huge trees are seldom so close together that a tank cannot move between them, but the space between them is often filled by smaller trees or brush. Closely spaced trees are usually fairly small and can be pushed over by a tank; however, the resulting pileup of vegetation may stop the tank. Trees that can stop a wheeled vehicle are usually too closely spaced to bypass. The pileup effect from pushing over vegetation is greater for wheeled vehicles than for tanks.

Trees are classified as either deciduous (broadleaf) or coniferous (evergreen). With the exception of species growing in tropical areas and a few species existing in temperate climates, most broadleaf trees lose their leaves in the fall and become dormant until the early spring. Needleleaf trees do not normally lose their leaves and exhibit only small seasonal changes.

Woodlands or forests are classified according to the dominant local tree type. A forest is classified as either deciduous or coniferous if it contains at least 60 percent of that species. Wooded areas that contain less than a 60 percent mixture of either species are classified as a mixed forest.

Scrubs include a variety of trees that have had their growth stunted because of soil or climatic conditions. Shrubs comprise the undergrowth in open forests, but in arid and semiarid areas they are the dominant vegetation. Shrubs normally offer no serious obstacle to movement and provide good concealment from ground observation; however, they may restrict fields of fire.

For terrain intelligence purposes, grass more than 1 meter high is considered tall. Grass often improves the trafficability of soils. Very tall grass may provide concealment for foot troops. Foot movement in savannah grasslands is slow and tiring; vehicular movement is easy; and observation from the air is easy.

Field crops constitute the predominant class of cultivated vegetation. Vine crops and orchards are common but not widespread, and tree plantations are found in relatively few areas. The size of cultivated areas ranges from paddies covering a quarter of an acre to vast wheat fields extending for thousands of acres.

In a densely populated agricultural area where all arable land is used for the crop producing the highest yield, it may be possible to predict the nature of the soils from information about the predominant crop. Rice, for example, requires fine-textured soils, while other crops generally must have firm, well-drained land. An area of orchards or plantations usually consists of rows of evenly spaced trees, showing evidence of planned planting. This can be distinguished on an aerial photograph. Usually such an area is free of underbrush and vines. Rice fields are flooded areas surrounded by low dikes or walls.

Some crops, such as grain, improve the trafficability of soils, while others, such as vineyards, present a tangled maze of poles and wires and create definite obstacles to vehicles and dismounted troops. Wheeled vehicles and some tracked vehicles are unable to cross flooded paddy fields, although they can negotiate them when the fields are drained and dry or frozen. Sown crops, such as wheat, barley, oats, and rye, will have a different impact on movement and concealment than those crops planted in furrows, because they are on a flat surface.

Photographic Texture

Texture is influenced by several variables, including crown shapes, tree spacing, and tree height. Texture interpretation as a means of identifying forest type requires knowledge of the texture often associated with each forest type. This knowledge is acquired through hands-on experience or the use of vegetation keys. With hands-on experience working with aerial imagery over along period of time and through the process of trial and error, an analyst can develop a mental catalog to relate texture in a given geographic area to a specific forest type.

Vegetation keys have been developed through the same trial and error process but have been documented and are available in the literature. They can be very useful in certain instances (see Chapter 3 for examples). However, one must remember that background knowledge of the area of interest is essential and most keys are specific to tree species, geographic area, time of year, film type, and photoscale. When using color or color infrared film, tone is often referred to as hue and is represented as shades of the color image.

Photographic Tone

Tone is also very important and is often applied to the problem of forest type identification. Tone is influenced primarily by stand density, reflectivity, and location of the tree stand with respect to the photographic center. When using panchromatic and black and white infrared film, photographic tone is represented by shades of gray. For example, in most regions of the world, needle leaf trees will appear darker in tone than broadleaf trees on panchromatic film given equivalent stand density. This tone difference is due to higher reflectivity of broadleaf trees in the region of the electromagnetic spectrum to which the film is sensitive.

SOIL FEATURES

Since soils vary in their ability to bear weight, their ability to withstand vehicle passes, and their ease of digging, military planners rely heavily on soil analyses. Soil type, drainage characteristics, and moisture content affect road construction, material location, and trafficability determination. The soil factor overlay breaks down the most probable soil types, characteristics, and distribution.

Describing and classifying soil normally requires exhaustive field sampling and the expertise of soil scientists. Terrain analysts, however, can produce acceptable soil factor overlays by examining maps, other factor overlays, aerial photographs, lab analyses, boring logs, and literature. The reliability of the resulting soil factor overlays will vary with the reliability of the sources used and the analyst's ability to correlate and combine the information correctly.

Determining whether a particular soil will support vehicle passage or the construction of roads and airfields is just a part of the terrain analyst's job. Since analysts also provide information on construction materials associated with roads and airfields, they need a variety of evaluation methods and a good working knowledge of the physical properties of soil.

Type Determination

For field identification and classification, soils may be grouped into five principal types: gravel, sand, silt, clay, and organic matter. These types seldom exist separately but are found in mixtures of various proportions, each contributing its characteristics to the mixture. Some soils may gain strength under traffic while others lose it.

Gravel is angular to rounded, bulky rock particles ranging in size from about 0.6 to 7.6 cm ($\frac{1}{4}$ to 3 inches) in diameter. It is classified as coarse or fine; well or poorly graded; and angular, flat, or rounded. Next to solid bedrock, well-graded and compacted gravel is the most stable natural foundation material. Weather has little or no effect on its trafficability. It offers excellent traction for tracked vehicles; however, if not mixed with other soil, the loose particles may roll under pressure, hampering the movement of wheeled vehicles.

Sand consists of rock grains from about 0.6 cm ($\frac{1}{4}$ inch) and smaller. It is classified as coarse, medium, or fine, and is angular or rounded. Well-graded angular sand is desirable for concrete aggregate and for foundation material. It is easy to drain and ordinarily not affected by frost action or moisture. Analysts must be careful, however, to distinguish between a fine sand and silt. When wet enough to become compacted or when mixed with clay, sand provides excellent trafficability. Very dry, loose sand is an obstacle to vehicles, particularly on slopes. Under wet conditions, remoldable sands react to traffic as to fine-grained soils. They feel somewhat plastic rather than gritty when rolled between the fingers.

Silt consists of natural reek grains. It lacks plasticity and possesses little or no cohesion when dry. Because of silt's instability, water will cause it to become soft or to change to a "quick" condition. When dry, silt provides excellent trafficability, although it is very dusty. However, it absorbs water quickly and turns to a deep, soft mud (a quick condition), which is a definite obstacle to movement. When

ground water or seepage is present, silt exposed to frost action is subject to ice accumulation and consequent heaving.

Clay generally consists of microscopic particles. Its plasticity and adhesiveness are outstanding characteristics. Depending on mineral composition and proportion of coarser grains, clays vary from lean (low plasticity) to fat (high plasticity). Many clays which are brittle or stiff in their undisturbed state become soft and plastic when worked. When thoroughly dry, clay provides a hard surface with excellent trafficability; however, it is seldom dry except in arid climates. It absorbs water very slowly but takes a long time to dry and is very sticky and slippery. Slopes with a clay surface are difficult or impassable, and deep ruts form rapidly on level ground. A combination of silt and clay makes a particularly poor surface when wet.

Chemically deposited and organic sediments are classified on the basis of mode and source of sedimentations. The identification of highly organic soil is relatively easy; it contains partially decayed grass, twigs, leaves, and so forth, and has a characteristic dark brown to black color, a spongy feel, and fibrous texture.

Classification

The terrain analyst uses the field classification technique to determine if the soil is fine or coarse or if it is remoldable sand. Usually the first two steps will determine the grain. If it is squeezed and rolled between the fingertips, fine-grained plastic soil will feel soft and smooth and should produce a ribbon or thread. Remoldable sands will feel coarser and more abrasive than a fine-grained material.

Unified Soil Classification System (USCS)

The Unified Soil Classification System uses a system of two-letter abbreviations to describe the soil. The primary letter identifies the predominant soil fraction. The secondary letter further describes the characteristics of the predominant soil fraction. The percent of gravel, sand, and fines provides the information necessary to choose the primary letter. See Figure 1-1.

Physical Tests

Before analysts classify soil, they must make four physical tests: gradation, liquid limit, plastic limit, and odor test.

Gradation, or grain-size distribution of a soil, is determined by a sieve analysis. A sieve analysis is the separation of soil into its fractions. It is made to determine gradation of material retained on a No. 200 sieve. It indicates whether a soil is well or poorly graded, and it will show the percentage of fines present. The sieve analysis may be performed directly on soils that may be readily separated from the coarser particles.

Sieves that military engineers commonly use have square openings and are designated as 2-, 1½-, 1-, ¾-, and ¼-inch sieves. They also use the US standard numbers 4, 10, 20, 40, 60, 100, and 200 sieves. See Figure 1-2 for an example of a sieve analysis.

PRIMARY LETTERS

- G--Gravel

- S-Sand
 - C-Clay (Used only with fine-grained soil with 50% fines or greater)
 - M-Silt
 - O-Organic
- SECONDARY LETTERS
- W-Well graded (Used to describe sands containing less than 12% fines)
 - P-Poorly graded
 - M-Silty Fines (Used with sands and gravels containing less than 5% but more than or equal to 50% fines)
 - C-Clay-based
 - L-Low Compressibility (Used to describe fine-grained soils (silts, clays, organics))
 - H-High Compressibility

As soil becomes more moist, it transforms from a plastic to a liquid state. The liquid limit is the moisture content at which a soil will just begin to flow when jarred slightly. In conjunction with the plastic limit, it is valuable in proper identification and classification of fine-grained soils. The liquid limit is usually expressed as a whole number and is obtained by performing the Atterberg liquid limit test, which is outlined in TM 5-530.

The plastic limit is the moisture content at which cohesive soil passes from a semisolid to a plastic state. A soil or soil fraction is called plastic if, at some water

content, it can be rolled out into thin threads. The moisture content ranges between a soil sample's liquid and plastic limits. The larger the plasticity index, the more plastic the soil ($PI = LL - PL$). The percent of moisture content, by weight, at which a 1/8-inch diameter thread begins to crumble is expressed as a whole number when recorded

Note: Gravels will be retained at ¾ - to 2-inch sieves, sands at Numbers 4-100; all fines will be retained at the No. 200 sieve, allowing estimation of percentages of soil categories.

Since practically all fine-grained soils contain some clay, most of them will exhibit some amount of plasticity. Soil plasticity is determined by measuring the different states a plastic soil undergoes with changing moisture content. When a fine-grained soil or remoldable sand sample is rolled between two flat surfaces or between one's thumb and forefinger, it forms a thread. Highly plastic and nonplastic soils break into short lengths or cannot be formed into ribbons. In the field, analysts can examine the shape and mineral compositions of coarse-grained soil by spreading a dry sample on a flat surface, separating the gravel and fines as much as possible, and estimating the percentages of each. TM 5-530 gives further information.

Organic soils of the OL and OH groups usually have a distinct odor, which can be used to aid in identification. This color is especially apparent in fresh samples. It is gradually reduced when exposed to air, but can be brought out again by heating a wet sample.

Field Identification

Normally, laboratory equipment will not be available in the field, but analysts can estimate and tentatively classify without tests. Classifications made under stricter conditions will be more accurate. We classify soils by particle size distribution. Where these soil types occur and the amount of area they cover often determine the suitability of an area for military operations. In general, we prefer coarse-grained soils for construction and cross-country movements.

Well-graded and poorly-graded soils can usually be distinguished by comparing the sizes. Poorly-graded soils, however, are more difficult to classify because they lack one size particle. Principal aids to soil identification and classification are the shaking test, the dry strength or breaking test, and gully analysis.

Analysts performing the shaking test will alternately shake a wet portion of soil in the palm of the hand and squeeze between the fingers. Atypical inorganic silt will become livery, show free water to disappear from silt soil, and cause the sample to stiffen and crumble under increasing finger pressure. If the water content is just right, shaking the broken pieces will cause them to liquefy and flow together. The portion will change its consistency and the water on the surface will appear or disappear at a rapid, sluggish, slow, or no-reaction speed. A rapid reaction to this test is typical for a nonplastic, uniform fine sand, inorganic silt, or diatomaceous (algae-based) earths. A sluggish reaction indicates slightly plastic inorganic and organic silts, or very silty clays. An extremely slow or no reaction to the shaking test is typical for all clays that plot above the A-line on the plasticity chart as well as for highly plastic organic clays.

The dry strength test readily distinguishes between plastic clays and nonplastic silts or fine sands. Analysts perform the dry strength or breaking test only on a small portion of soil, about ½-inch thick and 1½ inches in diameter, that passes the Number 40 sieve. They prepare this by molding a portion of wet plastic soil into the size and shape desired and allowing it to air (NOT oven) dry. After the sample is thoroughly dry, they will attempt to break the soil using their thumbs and forefingers. If it breaks, they will try to powder it by rubbing the particles together. Typical reactions obtained in this test for various types of soil are--

- Very highly plastic soil, or very high dry strength. Samples cannot be broken or powdered by finger pressure.
- Highly plastic soil, or high dry strength. Samples will break with great effort, but they cannot be powdered.
- Medium plastic soil, or medium dry strength. Samples will break and powder with some effort.
- Slightly plastic soil, or low dry strength. Samples will break and powder easily.
- Nonplastic soil, or very little or no dry strength. Samples crumble and powder on being picked up.

Gullies, sometimes called head water channels, result from erosion caused by water runoff. They develop in places where water cannot easily filter into the ground; therefore, it collects and flows in rivulets across the land surface. Gully analysis can be of great assistance in determining soil types, since these rivulets often take the shape peculiar to the material over which they flow. Since fine-grained silts and clays are relatively impervious soils, many gullies develop on their surfaces. Sands and gravels are rather permeable, and few or no gullies form.

Other factors that govern the extent of gully formation in an area are climate, vegetation, ground slope, and gradient of individual gullies. Gradient is more important than intensity, or number, of gullies in revealing soil conditions. The types of gullies that may be formed in various soil types are--

- Gullies in clay. They have a long, uniform, gentle gradient and are smoothly rounded. Clay soils are impervious and cohesive and often have a well-developed gully system.
- Gullies in silt (primarily loess). They take the form of a U and have steep sides and generally flat bottoms. The gradient is steep at the head of the gully but becomes more gentle a short distance away.
- Gullies in sand-clay. They are similar to gullies in silts but are more U-shaped, with a rounded rather than flat bottom. The gradient is nearly vertical at the head of the gully but levels off rapidly to a very gentle slope.
- Gullies in gravel, sand, or well-graded mixtures with some clays. They are usually well-defined, short, straight notches (ditches). The cross section is a sharp V with a uniform gradient. The steeper gradients are associated with the coarser materials. See Figure 1-3.

WATER FEATURES

Safe water, in sufficient amounts, is strategically and tactically important to Army operations. Water that is not properly treated can spread diseases. The control of and access to water is critical for drinking, sanitation, construction, vehicle operation, and other military operations. Military planners are concerned with areas with the highest possibilities for locating usable ground water. They must consider all feasible sources and methods for developing sources when making plans for water supply. Quantity and quality are important considerations. Terrain analysts can use the methods and systems available to locate both surface and subsurface water resources.

Figure 1-3. Gully profiles

Quantity

Water quantity depends on the climate of the area. Plains, hills, and vegetation are good indicators of water sources.

Large springs are the best sources of water in karstic plains and plateaus. Wells may produce large amounts if they tap underground streams. Shallow wells in low-lying lava plains normally produce large quantities of ground water. In lava uplands, water is more difficult to find, wells are harder to develop, and careful prospecting is necessary to obtain adequate supplies. In wells near the seacoast, excessive withdrawal of freshwater may lower the water table, allowing infiltration of saltwater that ruins the well and the surrounding aquifer.

Springs and wells near the base of volcanic cones may yield fair quantities of water, but elsewhere in volcanic cones the ground water is too far below the surface for drilling to be practicable. Plains and plateaus in arid climates generally yield small, highly mineralized quantities of ground water. In semiarid climates, following a severe drought, an apparently dry streambed frequently may yield considerable amounts of excellent subsurface water. Ground water is abundant in the plains of humid tropical regions, but it is usually polluted. In arctic and subarctic plains, wells and springs fed by ground water above the permafrost are dependable only in summer; some of the sources freeze in winter, and subterranean channels and outlets may shift in location. Wells that penetrate aquifers within or below the permafrost are good sources of perennial supply.

Adequate supplies of ground water are hard to obtain in hills and mountains composed of gneiss, granite, and granite-like rocks. They may contain springs and shallow wells that will yield water in small amounts.

Tree species can also indicate local ground water table presence. Deciduous trees tend to have far-reaching root systems indicating a water table close to the ground surface. Coniferous trees tend to have deep root systems, which depict the ground water table as being farther away from the ground surface. In desert environments, vegetation is scant and specialized to withstand the stress of desert life. Vegetation type is dependent on the water table of that location. Palm trees indicate water within 2 or 3 feet, salt grass indicates water within 6 feet, and cottonwood and willow trees indicate water within 10 to 12 feet. The common sage, greasewood, and cactus do not indicate water levels.

Quality

Quality will vary according to the source and the season, the kind and amount of bacteria, and the presence of dissolved matter or sediment. Color, turbidity, odor, taste, mineral content, and contamination determine the quality of water. Brackish water is found in many regions throughout the world but most frequently along sea coasts or as ground water in arid or semiarid climates.

Contamination

Potable water is free from disease-causing organisms and excessive amounts of mineral and organic matter, toxic chemicals, and radioactivity. Although surface water is ordinarily more contaminated than other sources, it is commonly selected for use in the field because it is more accessible in the quantity required. Ground water is usually less contaminated than surface water and is, therefore, a more desirable water source. However, the use of ground water by combat units is usually limited unless existing wells are available. Rain, melted snow, or melted ice may be used in special instances where neither surface nor ground water is available. Water from these sources must be disinfected before drinking.

Pollution

Water may be contaminated but not polluted. Streams in inhabited regions are commonly polluted, with the sediment greatest during flood stages. Streams fed by lakes and springs with a uniform flow are usually clear and vary less in quality than do those fed mainly by surface runoff. Generally, the quality of water in large lakes is excellent, with the purity increasing with the distance from the shore. Very shallow lakes and small ponds are usually polluted.

Porosity and Permeability

The water-bearing capability of a natural material is determined by porosity and permeability. The amount of porosity depends on the number of open spaces in the material. The permeability of rock is its capacity for transmitting a fluid. Rock types vary greatly in size, number, arrangement of pore spaces, and ability to contain and yield water. The amount of permeability depends on the degree of porosity, the size and shape of the interconnections between the pores, and the extent of the pore system. The geometric shapes of gullies can help identify the degree of permeability and porosity.

Drainage

Surface

Most military problems involving surface water arise because stream drainage conditions vary not only from place to place but seasonally as well. Military planners are concerned with the flow and channel characteristics of surface waters and their effect on military operations. The water constitutes obstacles to cross-country movement or, when sufficiently frozen, it may provide movement. They also determine the types of equipment to be used in an area.

Drainage data on all of the surface water features is significant to any aspect of military operations. Commanders must know the width and depth of streams and canals; the velocity and discharge of streams; which areas are subject to flooding, or are permanently wet, densely ditched, or canalized; the location of dams; and any other drainage feature that may be significant.

Although surface drainage is considered a standard product, subsurface drainage is not. Potential ground water indicators include the following:

- Crop irrigation
- Karst topography
- Snowmelt patterns
- Wetlands
- Vegetation
- Springs
- Soil moisture
- Surface water
- Wells/Qanats
- Built-up areas (local municipalities and populus)

Surface water resources are generally more accessible and adequate in plains and plateaus than in mountains. Large amounts of good quality water can normally be obtained in coastal areas, valleys, or alluvial and glacial plains. Although large quantities are available in delta plains, the water may be brackish or salty. Water supplies are scarce on lacustrine, loess, volcanic, and karst plains. In the plains of arid regions, water usually cannot be obtained in quantities required by a modern army; much that is available is highly mineralized. In the plains and plateaus of humid tropical regions, surface water is abundant but is generally polluted and requires treatment. Perennial surface water supplies are difficult to obtain in arctic regions; in summer it is abundant but often polluted.

Subsurface

Ground water, or subsurface drainage, is obtained without difficulty from unconsolidated or poorly consolidated materials in alluvial valleys and plains, streams and coastal terraces, glacial outwash plains, and alluvial basins in mountainous regions. Areas of sedimentary and permeable igneous rocks may have fair to excellent aquifers, although they do not usually provide as much ground water as areas composed of unconsolidated materials. Large amounts of good-quality ground water may be obtained at shallow depths from the alluvial plains of valleys and coasts and in somewhat greater depths in their terraces. Aquifers underlying the surface of inland sedimentary plains and basins also provide adequate amounts of water. Abundant quantities of good-quality water generally can be obtained from shallow to deep wells in glacial plains. In loess plains and plateaus, small

amounts of water may be secured from shallow wells, but these supplies are apt to fluctuate seasonally. Well water is usually clear and low in organic impurity but may be high in dissolved mineral content.

Patterns

The pattern of stream erosion usually gives an indication of rock structure and composition and an indication of whether the region is underlined by one or several rock types. The pattern can be dendritic, trellis, radial, annular, parallel, or rectangular.

The dendritic drainage pattern is a tree-like pattern composed of branching tributaries to a main stream, characteristic of essentially flat-lying and homogeneous rocks. This pattern implies that the area was originally flat and is composed of relatively uniform materials. Dendritic drainage is also typical of glacial till, tidal marshes, and localized areas in sandy coastal plains. The difference in texture or density of a dendritic pattern may help identify surface materials and organic areas.

In a trellis pattern, the mainstream runs parallel, and small streams flow and join at right angles. This pattern is found in areas where sedimentary or metamorphic rocks have been folded.

In a radial pattern, streams flow outward from a high central area. This pattern is found on domes, volcanic cones, and round hills. However, the sides of a dome or volcano might have a radial drainage system while the pattern inside a volcanic cone might be centripetal, converging toward the center of the depression.

The annular pattern is a modified form of the radial drainage system, found where sedimentary rocks are upturned by a dome structure. In this pattern, streams circle around a high central area. The granitic dome drainage channels may follow a circular path around the base of the dome when it is surrounded by tilted beds.

In the parallel pattern, major streams flow side by side in the direction of the regional slope. Parallel streams are indicative of gently dipping beds or uniformly sloping topography. The greater the slope, the more nearly parallel the drainage and the straighter the flow. Local areas of lava flows often have parallel drainage, even though the regional pattern may be radial. Alluvial fans may also exhibit parallel drainage, but the pattern may be locally influenced by faults or jointing. Coastal plains, because of their slope toward the sea, develop parallel drainage overboard regions.

The rectangular drainage pattern is a specific type of angular drainage and is usually a minor pattern associated with a major type such as dendritic. This pattern is characterized by abrupt bends in streams and develops where a tree-like drainage pattern prevails over a broad region. It is caused by faulting or jointing and is generally associated with massive igneous rock. Metamorphic rock surfaces, particularly those comprised of schist and slate, commonly have rectangular drainage. Slate possesses a particularly finely textured system. Its drainage pattern is extremely angular and has easily recognizable short gullies that are locally parallel.

Figure 1-4. Typical drainage patterns

Density

A determination of the density of the drainage pattern, or the number of streams in a precise area, is very beneficial. The nature of the drainage pattern in an area will provide a strong indicator of the particle size of the soils that have developed.

Surface sediments have good internal drainage. Sandstone, for example, due to its porosity and permeability, has good internal drainage. Water can usually percolate down through the soil and underlying rock, and the surface runoff will be at a minimum. The texture or density of the drainage pattern that develops on sandstone will be coarse.

A porous rock is not necessarily permeable. Clay, for example, contains up to 90 percent water and is very porous but is not permeable because of the nature of its flat-lying particles.

Sands and gravels are usually both porous and permeable, depending on sorting. When precipitation occurs, some of the water can percolate down through the sediment.

Shale is a relatively impermeable rock and has poor internal drainage. Surface runoff will be at a maximum, and erosion will often be intense. The texture or density of the drainage pattern that develops on shale will be fine-textured. See Figure 1-4.

OBSTACLES

Classification

An obstacle is any natural or man-made terrain feature that slows, diverts, or stops the movement of personnel or vehicles. Obstacles are classified as natural, such as escarpments, or man-made, such as built-up areas and cemeteries. They are further categorized as existing-present natural or as man-made terrain features that will limit mobility or as reinforced-existing features that man has enhanced to use as obstacles, such as gentle slopes reinforced by tank ditches, pikes, or revetments that limit mobility of maneuver units.

For classification purposes, obstacles must be at least 1.5 meters high and 250 meters long and have a slope greater than 45 percent (that which military vehicles are unable to travel). Obstacles that will be delineated should be in areas where they are of primary importance for the diversion of crosscountry movement. Obstacles include escarpments, embankments, road cuts and fills, depressions, fences, walls, hedgerows, and moats.

An obstacle factor overlay portrays linear terrain features that form natural obstacles not normally identifiable on a topographic map. Obstacles located in areas of dense forest, on steep slopes (greater than 45 percent), or within the gap width of streams normally will not be shown on the obstacle overlay. Hydrologic obstacles such as drainage ditches, channelized streams, and water banks are shown on the surface drainage overlay.

Identification

Escarpments are terrain features similar to cliffs and ridges and appear on aerial photographs as sharp breaks in the slope separating near level or gently sloping surfaces. They are hazardous to both troop and vehicle movement due to the sharp drop in the land typical of cliffs and ridges. Embankments are artificial structures, usually of earth or gravel, constructed above natural ground surfaces such as dikes, levees, and seawalls. Escarpments and embankments are tactically significant because explosive devices can make the road, railroad, or cross-country route impassable and because they can be used as channelization factors. This is especially true if the bypass capability is restrictive to the state of the ground.

Railroad and road cuts and fills restrict military movement. Cuts are thoroughfares or passages constructed through high areas. Fills are surfaces that have been built up or raised to bring a low area up to the same level as the surrounding surfaces.

Depressions are low points or sinkholes surrounded by higher ground. They usually have slopes equal to or greater than 45 percent, which will impede movement across the terrain. Pits, quarries, and sinkholes are typical examples of depressions.

Man-made features include fences or walls, hedgerows, and moats. Fences and walls are usually constructed to separate or restrict crossings from one plot of land to another. Hedgerows are tree-type barriers that can be identified by looking for closely spaced rows of trees or bushes planted on a mound. They are so dense that they restrict vehicle movement.

European vineyards offer an excellent example of obstacles, due to the wet state of the ground and the wire used to support crop growth. Combined with the existing terrain, vineyards cause extreme difficulty in cross-country mobility.

Finally, moats are landforms that appear on photos as wide trenches or ditches which usually surround a structure or prominent feature and are inaccessible to vehicles. Moats are generally restricted to the British or European areas. Preliminary identification can be made by referring to the map legend on a topographic map.

Man-Made Features

Chapter 2

URBAN AREAS

Urban-area intelligence is important in planning tactical and strategical operations, targeting for nuclear or air attack, and planning logistical support for operations. Knowledge of characteristics in urban areas may also be important in civil affairs, intelligence, and counterintelligence operations. Although information is frequently accessible, the amount of detail required necessitates a substantial collection effort.

The first aspect of urban intelligence includes geographic location, relative economic and political importance of urban areas in the national structure, and physical dimensions such as street shapes. The six street patterns are rectangular, radial, concentric, contour conforming, medieval irregular, and planned irregular (in the new residential suburbs of some countries).

The second aspect includes physical composition, vulnerability, accessibility, productive capacity, and military resources of individual urban areas. Urban areas are significant as military objectives or targets and as bases of operations. They may be one or a combination of power centers (political, economic, military); industrial production centers; service centers; transportation centers; population centers; service centers (distribution points for fuels, power, water, raw materials, food, manufactured goods); or cultural and scientific centers (seats of thought and learning, and focal points of modern technological developments).

Buildings can provide numerous concealed positions for the infantry. Armored vehicles can find isolated positions under archways or inside small industrial or commercial structures. Thick masonry, stone, or brick walls offer excellent protection from direct fire, and ceilings for individual fire. Cover and concealment can also be provided by the percentage of roof coverage. For detailed information, see FM 90-10.

Although an urban overlay is not a standard product, it is useful for military purposes. A subdivision can describe individual categories or break down a division to more specific items as required by the user, as long as the subdivisions are outlined in the legend. The division numbers in this manual are based on the DFAD system, in PS/ICE/200. The first number describes the division as residential or industrial, the second number indicates the type of construction material,

and the third number is the type of structure. If this number or its subdivisions are not needed in particular overlays, the number will be followed by zeros.

The industrial category (code 100) consists of the area and facilities that include the buildings used by those establishments engaged in the extraction, processing, and production of intermediate and finished products or raw materials. The two plant types in industrial areas are heavy manufacturing and medium and light manufacturing. Heavy-manufacturing plants require distinctive structures, such as blast furnaces, that could be readily recognized, while medium and light plants are housed in general loft buildings from which machinery could be removed. The specific type of medium-or light-manufacturing plant is not usually apparent from the type of building.

The transportation category (code 200) consists of the area and facilities used in moving materials and people on land. Features include railroads, roads, road interchanges, bridges, bridge structures, and conduits.

The commercial/recreational category (code 300) consists of the area and buildings where the major business activities and recreational facilities comprise the congested commercial core of a city. It includes retail and wholesale establishments, financial institutions, office buildings, and hotels. Modern multistory office buildings are typical of commercial sections of large cities. More than one commercial area may exist, particularly in cities where a number of towns have merged. Recreational activities, such as amusement parks and stadiums, may also be present.

Residential areas of a city (code 400) consist of the area and associated buildings where civilians live. They include many types of dwelling structures. Buildings vary from one and two-story single family dwellings to multistory apartment houses and may be built of any materials available locally. Types and sizes of residential areas often indicate the number of people and the varying living standards throughout the city.

Communication facilities (code 500) transmit information from place to place. This category includes telephone, telegraph, and radio facilities, as well as other electronic features such as power line pylons and structures. These facilities include communication towers and buildings, as well as power transmission, observation, microwave, television, and radio towers.

The governmental and institutional category (code 600) consists of the area and facilities, primarily buildings, that constitute the seat of legal, administrative, or other governmental functions of a country or political subdivision. This category includes those buildings serving as public service institutions, such as universities, churches, and hospitals. Governmental and institutional areas may include buildings such as the capital; administrative centers such as ministries, departments, courts, legislative buildings, embassies, and police headquarters; educational, cultural, and scientific institutions such as schools, hospitals, universities, libraries, museums, theaters, research institutions and laboratories; and religious and historic structures such as churches, monuments, and shrines.

The military/civil category (code 700) consists of the area and facilities used by the air, naval, and ground forces for waging war, training, and transporting

nonmilitary goods and personnel by sea and air. Military areas usually include transportation, billeting, storage, airfields, and administration facilities. Since these are of strategic and tactical importance, they require as accurate a description as possible for urban-area intelligence.

The storage category (code 800) consists of the area and facilities used for holding or handling liquids or gases, bulk solids, and finished products. Examples are cylindrical and spherical storage tanks; closed storage such as silos and grain bins; open storage such as vehicle, ship, and aircraft storage areas and storage mounds such as coal or minerals.

The landforms, vegetation, and miscellaneous features category (code 900) describes the surface landscape characteristics or natural scenery features such as levees, walls, and fences. It includes beaches, recreation areas, farms, wooded areas, swamps, and vacant land. Extensive open areas within the city may be valuable military assets, particularly if they have roads and railroad lines nearby as well as access to electric and water supply facilities. Open areas on the outskirts of cities are the most immediately available land for military use. Features include snow or ice areas, vegetation such as orchards and vineyards, agricultural areas, and surface features such as embankments, fences, and cliffs.

TRANSPORTATION

Analysts preparing terrain studies must carefully evaluate all transportation facilities to determine their effect on proposed operations. Analysts may recommend destroying certain facilities or retaining them for future use. The entire transportation network must be considered in planning large-scale operations. An area with a dense transportation network, for example, is favorable for major offensives. Networks that are criss-crossed by canals and railroads and possess few roads will limit the use of wheeled vehicles and the maneuver of armor and motorized infantry.

The transportation facilities of an area consist of all highways, railways, and waterways over which troops or supplies can be moved. The importance of each area depends on the nature of the military operation involved. An army's ability to carry out its mission depends greatly on its transportation capabilities and facilities.

Highways

Features

Military interest in highway intelligence of a given area or country covers all physical characteristics of the existing road, track, and trail system. All associated structures and facilities necessary for movement and for protection of the routes, such as bridges, ferries, tunnels, and fords, are integral parts of the highway system. Planners must know where new routes will be needed to support an operation.

Road widths are given in meters. Measurements indicate the minimum width of the traveled way. Each road segment between intersections is assigned a width value, and that number is placed parallel to the road segment.

The severe abuse given to roads by large volumes of heavy traffic, important bridges, intersections, and narrow defiles makes them primary targets for enemy

Figure 2-1. Parts of a road

bombardment. Planners must avoid maintaining unnecessary routes and must hold construction of new routes to a minimum.

Road Classification

Five road classifications are recognized on 1:50,000 scale topographic maps. They are all-weather, hard-surface dual/divided highway; all-weather, hard-surface highway; all-weather, loose-surface highway; fair-weather, loose-surface highway; and cart track.

All-weather, hard-surface, dual/divided highways normally have waterproof surfaces paved with concrete, bituminous surfacing, brick, or paving stone and are only slightly affected by precipitation or temperature changes. The route is never closed to traffic by weather conditions other than temporary snow or flood blockage. Photo interpretation keys include:

- Traveled portion of roadway is fairly straight.
- Even curves are present.
- Road width is uniform with easily seen parallel sides.
- Photo tint of road surface is an even color and varies from dark gray to white.
- Absence of ruts or holes on traveled portion of the roadway.

All-weather, hard-surface highways have waterproof surfaces of concrete, bitumen, brick, or paving stone and are only slightly affected by rain, frost, thaw, and heat. They are passable throughout the year to a volume of traffic never appreciably less than its maximum dry-weather capacity. They are never closed by weather conditions other than temporary snow or flood blockage. Photo interpretation keys are similar to those for the dual or divided highway.

All-weather, loose-surface highways are not waterproof but are graded and drained and are considerably affected by rain, frost, or thaw. They are constructed of crushed rock, water-bound macadam, gravel, broken stone and cinders, or

smoothed earth with an oil coating. The roads are kept open in bad weather to a volume of traffic considerably less than its maximum dry-weather capacity. Traffic may be halted for short periods of time. Heavy use during adverse weather conditions may cause complete collapse. Photo interpretation keys include:

- Sharp or irregular curves are present.
- Roadway meanders to avoid steep slopes.
- Gravel or crushed rock appears a uniform light gray except for low spots that collect water and appear in dark tones.
- Ruts and stones give the roadway a mottled appearance.
- Roadway edges and shoulders are not clean, sharp lines; sometimes, they are very difficult to determine.

Fair-weather, loose-surface highways are constructed of natural or stabilized soil, sand clay, shell, cinders, or disintegrated granite or rock. They include logging roads, abandoned roads, and corduroy roads which become quickly impassable in bad weather. Photo interpretation keys are similar to those for the all-weather, loose-surface highway except for less visible maintenance and narrower road widths at stream crossings.

Cart tracks are natural traveled ways including caravan routes and winter roads. They are not wide enough to accommodate four-wheeled military vehicles. Photo interpretation keys include

- Irregular turns and bends.
- Traveled roadway width varies.
- Apparent lack of direction.
- Roadway detours around wet terrain.

Railroads

Railways are a highly desirable adjunct to extended military operations. Their capabilities are of primary concern and are the subject of continuing studies by personnel at the highest levels.

Railroads include all fixed property belonging to a line, such as land, permanent way, and facilities necessary for the movement of traffic and protection of the permanent way. They include bridges, tunnels, snowsheds, galleries, ferries, and other structures.

Commanders need information on physical characteristics to determine railway capacities and maintenance or rehabilitation requirements. Railway intelligence covers all physical characteristics of the existing system and all available information pertaining to development, construction, and maintenance. Physical characteristics describe the railroad and its critical features and component parts such as roadbed, ballast, track, rails, and horizontal and vertical alignment.

Identification Keys

Railroads have definite characteristics distinguishing them from roads and highways (see Figure 2-2). Railroads often follow rivers, to take advantage of the normal gradual gradient of the valley. They follow as straight a line as possible, while roads meander. Curves are usually long and smooth, while roads may have sharp, right-angle turns and T-shaped intersections.

narrow. Wide gages are 5 feet or wider. They are mostly used by Russian, Finnish, and Spanish lines. Standard gages are 4 feet, 8½ inches. They are used for main and branch lines in the United States and the rest of Europe. Narrow gages are less than standard. Their use is somewhat limited to and usually found in mountainous, industrial, logging, and coastal defense areas and in mines and supply dumps. In South and Central America, the one-meter gage is found in many places; however, many of the countries are now adopting the standard gage because they import US-made rolling stock. See Figure 2-2.

Fixed Installations

Classification (marshaling) yards are used to sort freight cars. They are identified by a large group of parallel tracks with a restricted (one-or two-track) entrance and exit called a choke point. Active classification yards include numerous freight cars and small switch engines. Two or more classification yards are frequently found next to each other, with their entrances through a choke point. If this choke point is higher than either classification yard, it is known as a hump. Also, one yard is often placed slightly higher than the neighboring yard to allow cars to coast out of one yard through the choke point into a previously selected track of the other yard.

Service yards are normally found in or near marshaling yards and can be identified by the presence of roundhouses, turntables, service facilities, and car repair shops. Roundhouses are used for light repair and storage of locomotives. The number of roof vents on top of the roundhouse indicates the capacity of the roundhouse. Turntables are used for turning the engines around. Service facilities include coal towers, water towers, and coal piles. Car-repair shops normally appear as long, low buildings straddling one or more tracks, with cars awaiting repairs on sidings adjacent to the buildings.

Freight or loading yards are identified by loading platforms, freight stations, warehouses, and access to other means of transportation. Special loading stations are identified by grain elevators, coal and ore bins, oil storage tanks, and livestock pens with loading ramps.

Passenger stations vary from small rural depots or suburban stations to large stations and terminals. Small stations usually do not have loading docks and may not have parking areas for automobiles or trucks. They are located close to a track, and shelters may cover waiting platforms if more than two tracks pass the station. Large stations are identified by a large number of tracks leading into or past a large building that houses waiting rooms, ticket offices, and other passenger facilities. The track or boarding area is normally covered.

Freight stations may be identified by loading docks along railroad tracks on one side of a building and loading docks along a road or street on the opposite side. Freight stations are small, single structures near passenger stations designed for the temporary storage of goods received. Warehouses may be away from fixed railroad installations, and more than one may be located in an area. Freight cars loading or unloading at a freight station aid in identification of the installation. See Figure 2-3.

Figure 2-3. Fixed Installations

Rolling Stock

Locomotives. Locomotives vary greatly, from small switch engines 24 to 30 feet long to mainline passenger and freight locomotives 35 to 50 feet long. Locomotives longer than 50 feet are used for special purposes such as mountain climbing. Locomotives may be steam, electric, diesel, or diesel-electric. Steam locomotives are easily identified by smoke and steam around an operating locomotive, a smokestack, and a fuel tender attached just behind the locomotive. Electric locomotives have no fuel tender or smokestack and may be identified by overhead antennae if they receive their power from overhead lines. The lines may be evidenced by the shadows their support poles cast. Diesel locomotives lack a fuel tender and are usually identified by their streamlined appearance.

Freight cars. The boxcar is the most frequently found freight rolling stock, recognized by its rectangular shape and little roof detail. The round-topped freight car differs only in its top. These cars average 40 to 45 feet in length in the US, 25 feet in Europe. Other freight cars are the gondola and hopper cars, which are used for coal, ore, and other bulky material or large freight that cannot be loaded into a boxcar. Shape and shadow aid in identification. Refrigerator, stock, and automobile cars are so close in appearance to boxcars that low-level oblique arcs are usually necessary to distinguish them. Caboosees, not always found on foreign railroads, appear as small cars attached to the end of freight trains, usually with a visible cupola.

Passenger cars. For identification purposes, the outstanding characteristic of passenger cars is their length, especially when compared with freight cars. They vary from 50 to 80 feet. Normally, it is not possible to distinguish a coach from a sleeping or dining car.

Special Equipment. Railroads have a variety of special equipment in their rolling stock. The railcar is a self-contained unit with its own power plant as well as space for passengers or mail and baggage or all three. Cranes, snowplows, and drop-center flatcars are sometimes present on rolling stock.

Railheads

Railheads are points of supply transfer from railroads to other transportation and are generally found in small towns or cities where sidings and storage space already exist. Characteristics of a railhead are spurs and sidings from a main line; a road net, including narrow gage railroads, leading away from the area; piles of materials stacked near the track trucks or wagons or both, either without order or organized into convoys or trains; and temporary dwellings, such as tents or Quonset huts, for housing troops guarding and handling supplies.

End Points

System. A railroad system is a network of railroads operated by a single management entity, government or corporate. System end points are the points where a railroad system begins, ends, or changes identification. There may be no system end points within many map sheets, but system end points will always coincide with route and segment end points.

Route. A route is the portion of a system providing through lines between selected points. Routes are usually specified by the system management, but it

may often be convenient or appropriate for the analyst to select others. The route will be identified on the factor overlay by abbreviations of the two endpoints placed in parentheses. There may be no route end points within the area of a 1:50,000 factor overlay. Route end points always coincide with segment end points and may coincide with system end points. Kilometer distances are always measured from route end points.

Segment. A segment is the portion of a route characterized by uniform load-bearing, traffic capacity, and operating characteristics. Analysts will number segments sequentially along a route within a map sheet, starting at the segment nearest the zero kilometer point. End points of segments are defined by nodes along the route, at which anyone of the following conditions occurs:

- A change in the number of tracks (points where passing tracks or sidings start or end do not constitute nodes).
- A change in the gage of the track.
- A route or system terminal.
- The point where the route crosses the neat line of the factor overlay.
- A terminal or junction where traffic may be diverted onto another route.
- A change in the type of construction such that the load-bearing capacity, speed or traffic capacity is altered.
- A point where electrification starts, ends, or changes method of power transfer.
- A point where a change in traffic control methods occurs, such as international boundary crossings.

Number of Tracks

Analysts indicate the number of tracks for single- and double-track lines by the number of ticks used with the gage symbol. Routes with three or more tracks are symbolized by the double-track symbol supplemented by a *T* and a number, which indicates the actual number of tracks. Lines operated by different systems that closely parallel each other or share a common right-of-way are in juxtaposition (side by side) and are indicated by separate symbols. Symbols for such lines will be sufficiently displaced from the centerline to make it clear that two distinct lines exist.

Bridges

Features

Structures and crossings on highways or railways include bridges, culverts, tunnels, galleries, ferries, and fords. For the purpose of terrain intelligence, they also include cableways, tramways, and other features that may reduce or interrupt the traffic flow on a transportation route. Bridges and culverts are the structures most frequently encountered; however, any feature that may present a potential obstacle is significant in a military operation. See Figure 2-4.

Any type of structure or crossing on a transportation route is an important portion of the route regardless of the mode of transportation. Maps, charts, photographs, and other sources contain valuable information that analysts should exploit.

Highway and railway bridges and tunnels are vulnerable points on a line of communications. Information about prevention, destruction, or repair of a bridge may be the key to an effective defense or the successful penetration of an enemy

Structure Type	Span Type	Photo Indication	Photo Tone/Color/Texture	Probable Material Type
Bridge	 SUSPENSION BRIDGE	Towers Shadow outline of towers and suspension cables. Texture of tower surfaces.	Color: green, red, black Tone: dark gray	Steel reinforced concrete
	 TRUSS	Presence of superstructure cross hatch pattern of span members, detail visible from shadow detail.	Color: white, gray, red, silver Tone: light to dark gray Texture: rivet pattern	Steel
	 SLAB	Absence of superstructure Type of guard rails: (1) Angular (2) Rounded, smooth	Beam, girder, and slab bridge design preclude identification of construction material from vertical aerial photography. When possible the analyst should obtain low oblique photography of these types of bridges.	
	 BEAM	Absence of superstructure Type of guard rails: (1) Angular (2) Rounded, smooth, length		
	 GIRDER	Absence of superstructure Type guard rails: (1) Angular (2) Rounded, smooth, length, shadow detail		
	 ARCH (closed span/drel)	Shadow detail: massive structure	Color: white, red Tone: gray, light gray Texture: rough Joint patterns	Masonry structures are massive and usually old. Reinforced concrete spans are smaller.
	 ARCH (open span/drel)	Shadow detail: open structure, smooth, rounded span members	Color: white to light gray Tone: gray to light gray Texture: smooth	Smooth rounded span Members: reinforced concrete Angular span members: steel
Snowshed		Location: Mountainous areas Length	Color: light gray to white Tone: light gray Texture: smooth	Difficult to determine from vertical photo. Long structures (100m) are probably reinforced concrete.
Gallery		Location: limited to Mountain sides and valleys. Rock and landslide indications in area.	Roof materials not indicative of material.	Recent construction: reinforced concrete. Old structure: wood

Figure 2-4. Structure construction type identification from vertical aerial photography

area. A bridge seized intact has great value in offensive operations, since even a small bridge eases troop movement over a river or stream.

A bridge includes the substructure and superstructure. The substructure comprises the foundation and supporting elements of a bridge; the superstructure is the assembly that rests on the substructure and spans the gaps between ground supports.

Bridge superstructures take many forms, ranging from short trestle spans built into wooden stringers to large multiple cantilever spans of several thousand feet. Most have two basic components, the main supporting members and a floor or deck system. The primary exception is the concrete slab design, in which the supporting member also serves as the floor. The superstructure used depends on the loads to be carried, required span lengths, time available for erection, availability of

Figure 2-5. Bridge mensuration requirements

construction materials, manpower and equipment, and characteristics of the site. See Figure 2-5.

Based on their superstructures, bridges may be either fixed or movable. The five major categories of fixed bridges are beam, slab, girder, truss, and arch bridges. These types may occur alone or in combination. Movable bridges have at least one span that can be moved from its normal position to allow passage of vessels. The four general types of movable bridges are swing, lift, bascule, and retractile.

The load capacity is the most critical factor of a bridge. The most reliable capacity data comes from the standard design loadings by which most countries design their bridges. Usually a country has a number of standard design loadings for different capacity classes. Standard design loadings may be expressed by a letter, number, or symbol.

Bridge Reporting

The data base includes all on route bridges that can be identified and measured on aerial photography or derived from updated collateral sources. Structures less than 6 meters long are culverts; all others are treated as bridges. This cut-off length is flexible according to the prevalence of bridging in the study area.

All bridges present a potential restriction to traffic, and all items reflected in the collection checklist are important. Some of the basic requirements for information on any type of bridge are--

- Location, or kilometer stations from origin of section. The nearest kilometer should be given unless close spacing requires use of the nearest 0.1 kilometer for separate identifications.
- Obstacle crossed. Analysts must list the name of the stream when they know it. Other possible entries include gorge, railroad, and canal.
- Universal transverse mercator (UTM) coordinates to six places and geographic coordinates to the nearest second.
- Overall length, to the nearest meter. This should generally be the sum of the span lengths, but it should not include approaches.
- Roadway width to the nearest 0.1 meters of that portion of the deck over which vehicles normally run, excluding sidewalks, curves, parapets, truss superstructure, and so forth. Width is measured between the inside faces of the curbs.
- Horizontal clearance, or the limiting width to the nearest 0.1 meter at a point 30 centimeters above the edge of the roadway. This normally includes widths of curbs and sidewalks but excludes parapets and trusses. The horizontal clearance on a truss bridge is measured from a point 4 feet above the roadway.
- Vertical clearance, or the minimum distance between the roadway and any obstruction immediately over the roadway, to the nearest 0.1 meter. The letter *u*, for unlimited clearance, indicates no obstruction.
- Military load classification (MLC). This number indicates the carrying capacity of the bridge, including classifications for single- and double-flow traffic. The symbol to show the MLC is a circle with the bridge information on the inside. The load classification is on the top of the circle. In those instances where dual classifications for wheeled and tracked

vehicles exist, both classifications are shown. See TM 5-312 for further information. See the NATO bridge symbol on Figure 2-6.

- Spans. Both the number and length of spans need to be determined. Lengths are given to the nearest 0.1 meter and represent the distance between supports, or centers of bearing. The bridge classification is measured from center to center of supports and is based on the weakest span.
- Span construction. The construction material and type will be identified.
- Bypasses. Bypasses are local detours along a specified route that enable traffic to avoid an obstruction. They are classified as easy, difficult, or impossible according to the ease of access to the bridge bypass. See Figure 2-6.

Culverts

Culverts are grouped into four main categories of pipe, box, arch, and rail girder spans. Pipe culverts are the most common. They are usually concrete, but corrugated metal and cast iron are also used. The pipes have different shapes and range from 12 inches to several feet in diameter. Box culverts are used to a great extent in modern construction. They are rectangular in cross section and usually concrete. A large box culvert is similar to a slab bridge. Arch culverts were used frequently in the past but are rarely constructed now. They are concrete, masonry, brick, or timber. Rail girder spans are found on lightly built railways or, in an emergency, on any line. The rails are laid side by side and keyed head to base and may be used for spans of 3 meters or less.

Tunnels, Galleries, and Snowsheds

Features on a transportation route where it would be relatively easy to block traffic or that affect the traffic capacity of the road are critical. Such features include

Figure 2-6. Bridge Reconnaissance Report

Figure 2-7. Dimensions required for tunnels

tunnels, snowsheds, and galleries. These obstructions can prevent access to vehicles with certain physical dimensions. Reductions in traveled-way widths, such as narrow streets in built-up areas, drainage ditches, and embankments, can also limit vehicular movement. This is an important aspect of transportation intelligence.

Tunnels

A tunnel is an underground section of the route that has been bored or made by cut-and-cover for a route passage. It consists of the bore or bores, portals, and possibly a liner. Tunnel bores are commonly semicircular, elliptical, horseshoe, or square with arched ceiling. Bores may be lined with brick, masonry, or concrete, or they may be unlined. Some very long tunnels on steam-operated railroad lines are artificially ventilated by blowers at the portals or in ventilating shafts above the bore. Alignment of tunnels may be straight or curved. See Figure 2-7.

Galleries and Snowsheds

Built in rugged, mountainous terrain, these protective structures are not as common as bridges or tunnels. Galleries offer protection against snow and rock avalanches. They may be cut into the side of a cliff and have a natural overhang, or the cover may be a concrete slab, either of which guides the avalanche across the track or road. One side of a gallery is usually open. Snowsheds offer protection against snow accumulations and slides on exposed sections of the permanent way.

Ferries

Ferries or ferry boats convey traffic and cargo across a river to another water barrier. These vessels vary widely in physical appearance and capacity depending on the depth, width, and current of the stream and on the characteristics of traffic to be moved. Propulsion of ferries may be by oars, cable and pulleys, poles, or stream current such as trail and flying ferries, or by steam, gasoline, or diesel

LEGEND

1. Portal-to-portal length of tunnel
2. Center line distance of tunnel
3. Effective width of the traveled way, curb to curb
4. Horizontal clearance (minimum width of the tunnel bore measured at least four feet above the traveled way)
5. Overhead clearance (minimum distance between the top of the traveled way and the lower edge of the tunnel ceiling or any obstruction below the ceiling such as trolley wires or electric light wires)
6. Rise of tunnel arch (radius of curved portion)
7. Radius of curvature of the traveled way either measured or estimated
8. Gradient (percentage of rise of the traveled way between portals)
9. Change in gradient within the tunnel (percentage of rise each way from break of grade)

engines. Construction of ferry boats varies widely from expedient rafts to ocean-going vessels.

The capacity of a ferry boat is usually expressed in tons and total number of passengers and is sometimes assigned an MLC number. When more than one ferry is employed for a given site, report the capacity of each.

Climatic conditions have a marked effect on ferry conditions. Fog and ice substantially reduce the total traffic-moving capacity and increase the hazard of the water route. Therefore, data on tide fluctuations, freezing periods, floods, excessive dry spells, and their effects on ferry operations is important.

A ferry site is the place where ferries convey traffic and cargo. Ferry slips or piers are generally provided on the shore to permit easy loading. The slips may vary from simple log piers to elaborate terminal buildings. A common characteristic of ferry slips is a floating or adjustable approach ramp that accommodates variations in ferry deck level. Analysts must consider the limiting characteristics of ferry sites, such as the width of the water barrier from bank to bank, the distance and time traveled by the ferry boat from one side to the other, and the water depth at each ferry slip.

Approach routes to ferry sites have an important bearing on ferry use. Analysts should report the condition of the approaches, including the load-bearing capacity of landing facilities.

Fords

A ford is a location in a water barrier where the current, bottom, and approaches permit the passage of personnel or vehicles and other equipment, where little or no swimming is required, where they cross under their own or assisted propulsion, and where their wheels or tracks remain in contact with the bottom.

Fords are classified according to their crossing potential, or trafficability, for foot or wheeled and tracked vehicles. Fordable depths for vehicular traffic can be increased by suitable waterproofing or, in the case of modern tanks, by adding deep-water fording kits that permit fording depths up to 4.3 meters.

Approaches may be paved with concrete or bituminous surface material but are usually unimproved. Analysts should carefully note the composition and slope of approaches to a ford to permit determination of trafficability during inclement weather and after fording vehicles have saturated surface material.

Bottom conditions are determined by checking the stability and composition of the bed. The composition of the stream bottom determines its trafficability. In some cases, the natural river bottom of a ford may have been improved to increase load-bearing capacity and to reduce the water depth. Improved fords may have gravel or concrete surfacing, layers of sandbags, metal screening or matting, or timber or wooden planking.

Climatic conditions such as seasonal floods, excessive dry seasons, freezing, and other extremes of weather materially affect stream fordability. The velocity of the current and the presence of debris also affect the condition and passability of a ford.

Current estimates are swift (more than 1.5 meters per second), moderate (1 to 1.5 meters per second), and slow (less than 1 meter per second).

Low-water Bridges

Low-water bridges consist of two or more intermediate supports with concrete decking and are located wholly within ravines or gullies. **During** high-water periods, they may easily be confused with paved fords, as both are completely submerged. **Because** of corresponding military load limitations, analysts must properly identify low-water bridges and paved fords.

Cableways and Tramways

Cableways, tramways, and so forth are not usually major factors in a military operation; however, they may be encountered in rugged mountainous regions and beach areas or used as connections between two primary supply routes. In some cases they may extend for several miles and be the best available method for moving supplies.

Pipelines

Pipelines that carry petroleum and natural gas represent an important mode of transportation. While rail, water, and road transport are used extensively for transporting fluids and gases, the overland movement of petroleum and refined products is performed most economically and expeditiously by pipeline. Crude-oil pipelines are used only to transport crude oil, while many refined-product pipelines carry more than one product. These products are sent through the pipelines in tenders, or batches, to keep the amount of mixing to a minimum. **Because** of their most vital link in an industrialized country's energy supply system, coal and ore are also carried in pipelines as slurry.

Components

Pipes are used in long-distance pipelines and in many local lines. They are composed of welded steel with diameters varying from 15 centimeters to more than 1 meter, depending upon the economies of the line's construction. The pipe may be laid either underground or above ground **and** may extend cross-country or follow the alignment of roads and railroads. When a pipeline must cross a stream, the pipes are usually laid along the stream bottom. Where streams are **swift** or where beds may shift rapidly, either the pipe is attached to existing bridges **or special** pipeline suspension bridges are built. Siphon crossings are used where necessary,

When an increase or decrease of pressure is required, regulating features such as pumps or compressors are used. Pumping stations are used for liquid fuels and compressor stations for gas. They are similar in appearance except for the cooling towers present at compressor stations.

Valves, manifolds, and meters are integral parts of any pipeline system and are located at frequent intervals along the pipeline and at terminals. Valves protruding from the ground are often the only indicators of a pipeline alignment.

Terminal Facilities

Refinery terminals consist of numerous tanks for the separate storage of crude oil and refined products. Facility size and type depends on whether the refinery is located near the source of supply or consuming center. Refined-product dispensing terminals contain a variety of products for final distribution.

Natural gas is generally stored in bulk, below the ground, and under high-pressure. Large underground gas storage pools, usually caves or quarries near consuming centers, are often used to store gas for seasonal or emergency needs. Above ground, natural gas is stored mostly under pressure in spherical tanks, but large telescoping tanks are sometimes used for low-pressure storage. Natural-gas receiving terminals are located at the producing field and contain facilities for conditioning the gas for pipeline transmission. Natural-gas dispensing terminals are located at

Figure 2-8. Storage tanks - Shapes

Figure 2-9. Berthing facilities

consuming centers and include dispatching and metering facilities and sufficient storage facilities to meet peak demands.

Storage tanks, found in varying numbers at all petroleum installations, are easily recognized. Volatile products such as gasoline and kerosene are generally stored in floating roof tanks. These tanks have roofs that float on the liquid to reduce space in which vapor might form. Nonvolatile products such as fuel oils and crude oil are stored in fixed-roof tanks. Petroleum gases are generally liquefied and stored under pressure in spherical tanks or in horizontal cylindrical tanks. The number and variety of tanks in a storage installation indicate the quantity and types of product stored. Areas of great extent and capacity are called tank farms. See Figure 2-8.

PORTS AND HARBORS

Information about ports, naval bases, and shipyard facilities is essential for estimating capacities, vulnerability, and other items of military significance.

Ports

Ports are settlements with installations for handling waterborne shipping. Principal port facilities are berthing space, storage space, cargo-handling equipment, cargo transshipment facilities, and vessel-servicing facilities. Ports are classified on an areawide rather than a worldwide basis, and a principal port in a small

Figure 2-10. Annotated overlay of a European harbor (Kiel, Germany)

maritime nation may be equivalent to a much lesser port in the more extensive port system of another country. In wartime, principal and secondary ports and bases are prime targets for destruction, and the relative importance of minor ports increases. See Figure 2-9.

Ports may have various structures affording berthing space or may be anyplace a vessel may be made fast. These structures include piers, moles, and wharves or quays. Perhaps the most important difference between these structures is that piers are supported by pilings driven into the harbor bottom, while moles are of solid construction. In addition, wharves and quays are parallel with the shoreline, while piers and moles are perpendicular to it.

Harbors

Harbors are areas where the anchorage and shore are protected from the sea and storms by natural or man-made barriers. Areas that do not have this protection but are still suitable for vessel anchorage are open anchorages or roadsteads. A good harbor must have deep water, adequate protection from storms, enough space to accommodate large numbers of vessels, and a shoreline that can be developed as a port and as a site for industry. Harbors may be situated on the sea, estuaries, or inland lakes and rivers and may easily be recognized by abundant waterborne traffic and port facilities. See Figure 2-10.

Relatively few strategically located natural harbors are large enough or safe enough to be valuable to shipping. Many of the important harbors of the world are man-made. Most harbors have some or all of the more common artificial protective

structures. A breakwater is a massive stone or masonry structure extending across or at an angle to the entrance to the harbor. A jetty is the name applied to a breakwater that connects with the shore. A mole is a jetty that is wide enough to allow construction of a roadway along the top. A sea wall is a structure built along the coastline to prevent the sea from eroding the land.

Within the harbor itself are various types of buoys used as navigational aids. In addition, lighthouses, mooring buoys, and dolphins are often present. Mooring buoys are huge buoys located in the harbor so that vessels may tie up without dropping anchor. Only when a harbor has been developed for transacting business between ship and shore does it become part of a port. Dolphins are groups of pilings driven into the harbor bottom for the same purpose.

Dolphins usually consist of a cluster of piles lashed together at the top. They are located off shore and are used singly for mooring into or hauling out of a berth and in a series for mooring a ship alongside. Dolphin moorings conserve space in the stream and are used either for idle berthing or for loading cargo from lighters. Dolphins are often associated with a wharf either as a protective device at wharf corners or as a means of increasing the length of berthing space provided by a wharf face.

A dock, also called a slip or berth, is the water adjacent to a mole, pier, or wharf when that water area is narrow and affords berthing space. Basins are broad and expansive, artificially enclosed bodies of water that form a harbor or part of a harbor. They may be tidal basins in which water is subject to tidal influences, or controlled-level basins in which the water level is maintained irrespective of tidal change. Controlled-level basins are either wet docks or half-tide basins. A wet dock is enclosed by a gate, caisson, or lock. It may be filled by naturally impounding water at each high tide or at spring tides only. Pumping plants may be provided for initial filling or for elevations of the water above that achieved by natural impounding. The half-tide basin has gates at each end and is used in much the same manner as a large leak to increase the enormous amount of water required to raise the water level. It cannot be used at all states of the tide.

Harbor works, including protective works, are structures designed to provide shelter, control water flow, and regulate erosion for improvement of the navigability of a harbor. The principal structures are breakwaters, jetties, groins, sea walls, bulkheads, dikes, locks, and moles. Harbor works do not include port facilities that are designed specifically for transfer of cargo and the servicing ships.

Depths are important in such port topics as harbor, entrance, anchorage, wharves, and dry docks. They are computed in terms of established reference planes that are based on but do not necessarily coincide with tidal levels. The particular reference plane on which depths on a hydrographic chart are based is called chart data and is defined on the chart. Precise data is established for most ports and is a basis for soundings. Analysts should clearly indicate the reference plane when reporting depths.

The navigable waterways through the approach, the entrance to the harbor, and the harbor itself frequently determine the size of the ships (draft, length, beam, height above water) that can be accommodated in the port. Analysts should describe in detail any thruway with controlling dimensions that limit the size of

ships which can traverse it. Reports on the experiences of ships with critical dimensions that have entered are most helpful.

Cranes (Cargo-handling Equipment)

Cargo berthing space may be recognized by the presence of heavy handling equipment located on piers or wharves. However, very small ports may not have any such equipment, requiring vessels to supply and use their own. Port cargo-handling equipment includes various hoists for handling general cargo and special equipment for other cargo.

A gantry crane is a traveling crane on rails that consists of a hoist on a heavy cross girder supported at two points. Hoisting is performed by a trolley or crab that moves transversely along the bridge. Gantry cranes occasionally serve as a base for a jib crane, the latter being mounted on and capable of transverse movement along the bridge member. They are used extensively in shipyards for hull erection and in various industrial yards and shops for heavy lifting. They are almost always electrically operated. Depending on use, they may range up to 250 tons capacity. Hoisting capacity is constant regardless of the position of the crab or trolley on the bridge.

A cantilever crane consists of a base or tower structure on which is mounted a counterbalanced horizontal arm or jib. A trolley that can be racked along rails on the cantilevered jib carries the hoisting sheaves. The trolley does not carry the hoisting mechanism but merely serves to support the fall, and its transverse movement is controlled by a system of sheaves and ropes. Cantilever cranes are most commonly found in shipyards, although they may be used for cargo handling in special instances where a large working radius is required. They are normally electrically powered and range up to 250 tons or more in capacity. Capacities should be reported at maximum and minimum radius. One type of cantilever crane is the hammerhead. These cranes are supported at one point, about which the mechanism can turn. The hoisting end is balanced by a cab or counterweight. The entire machine may be mounted on rails for movement along the pier or wharf.

A jib crane consists of the primary arm on which is mounted a shorter arm, or jib, extending at an angle. At the end of the jib are sheaves through which run the fall from which the load is suspended. The fall is raised and lowered by a hoisting mechanism built into the crane. Jib cranes are frequently mounted on gantry, bridge, or trestle bases, where they are capable of transverse movement. Because of their versatility, they are the most common cranes and have a wide range of uses. They include wharf cranes for handling general cargo and many cranes used in shipyards. They are usually electrically powered and range in capacity from 3 to 5 tons. Other jib cranes may range up to 100 tons or more. Analysts customarily report the capacity at minimum working radius and at maximum radius. They must also indicate the maximum height of lift above the wharf deck for wharf cranes.

A floating crane is almost any crane mounted on pontoons or barges. The float may range from a simple wooden barge to an elaborately constructed steel hull with built-in balancing tanks and pumps. Large floating cranes, usually steam powered, are commonly used in harbor construction, salvage operations, or transfer of heavy cargo to and from ships. Capacity may exceed 400 tons. Small floating cranes, driven by internal combustion engines or operated manually, are used for many lifting tasks. The operating dimensions are reported similarly to those for shore

cranes, except that reach beyond the pontoon is substituted for radius. Dimensions of the pontoon include length, beam, draft forward, and draft aft.

A derrick consists of a vertical mast supporting a pivoting jib or boom. The mast may be stayed by cable or beams anchored to the ground, with the fall running through sheaves at the end of the jib. Large derricks are used for miscellaneous heavy-lifting tasks and run on steam, gasoline, diesel, or electricity. Small derricks are used for simple cargo handling and are operated manually or are driven by gasoline or diesel engines. Derricks and shearlegs are normally the simplest and least expensive cranes. Depending on size and type, capacity may range from 1 to 40 tons. The jib of a derrick functions similarly to that of a jib crane, and operating dimension should be reported the same way.

A shear-leg crane is a fixed hoisting device with a leaning tripod supporting the system of pulleys and cables. Heavy shear legs may range up to 150 tons capacity. In hoisting and lifting motions, the operating dimensions are comparable to those of the jib crane.

A locomotive crane may be recognized easily, because it is mounted on a special railroad flat car. A revolving elevated crane is mounted on a high, derrick-like structure that moves along rails. An overhead crane differs from a gantry crane in that the supporting mechanisms do not move as they do on the gantry. A bridge crane is constructed so that the crane may travel beyond each supporting leg.

Anchorage

Much of the anchorage data can best be shown on large-scale charts and plans. All available operational information should be reported, including anchorage designations and berth assignments by local authorities, normal anchoring practices, and ship experiences.

Fixed moorings may consist of anchored buoys or mooring posts. They are provided in harbors where space restrictions prohibit free-swinging anchorage, where the number of accommodations is limited, and when they provide a more secure berth than a ship's own anchors can provide.

Mooring buoys can provide several berth types, including free-swinging (one buoy), ship's head secured to buoy; bow and stem (one buoy), ship secured ahead by own anchors and astern to bollards ashore; bow and stem (two buoy), ship secured to buoys ahead and astern. Buoys may be held by a single anchor, but two or more anchors laid at varying angles are generally used for greater holding capacity and more precise positioning of the buoy. When more than one anchor is used, each may connect independently with the buoy secured by a pendant chain. Mooring buoys, particularly those used by naval craft, may be fitted with submarine cable connections for telephone, electricity, and water. The holding capacity of the buoy is important information.

Ships may lie infixed moorings without buoys in a variety of ways. The simplest method, that of mooring with one or both anchors ahead and stem lines to bollards ashore, is used where wharf facilities are limited, and is commonly used in Mediterranean ports.

Harbors are usually subject to sea and swell, and navigation and port operations are consequently affected. Duration and seasonal variation in sea and swell conditions are important factors to analysts, as are specific effects on lighterage and boat work on anchoring and mooring and on movement into and about the harbor.

Wharves

The majority of landing structures are either piers or wharves. Piers project into the water at an angle with the shoreline. Berthage is usually available on both sides of the pier and at the head as well, if the structure is wide enough. Variations of the simple straight pier are the T-head pier and the L-head pier. These piers are commonly used to transfer bulk petroleum, and berthage is generally confined to the pier head.

Wharves form the pivot point for port operations, and detailed information concerning them is necessary to evaluate a port's capabilities. Generally, wharves include all landing structures, even piers. Specifically, a wharf is a structure that parallels the shoreline and provides berthage at its face only. A wharf's design is determined largely by its intended use and by local conditions and engineering practice. Variations in names of landing structures cause considerable confusion, and analysts should be careful to use the proper term. The term *dock* is properly used in northwestern European countries to designate a water area; in the US, however, it is applied generally but erroneously to any and all types of landing structures. The pier structure is commonly called a jetty in British and other foreign ports, and all marginal structures are *quays*. Improper classification will often be embodied in the proper name of a wharf, but the reporting officer should not arbitrarily change the name. In describing the structure, however, the analyst should correctly indicate the wharf type.

The wharf type may be marginal, quay, or offshore. The marginal wharf and quay are both built parallel to and against the shore and differ only in construction type. The marginal wharf is constructed of open piling, while the quay is a solid wall of masonry or other material. The offshore wharf is a structure of open piling built parallel to but in an insular position off the shoreline. It may be connected with the shore by one or more approaches or gangways or pipelines. A variation of the offshore wharf commonly used in the Far East is the pontoon wharf, which consists of pontoons of various construction moored in a fixed position offshore and connected with the shore by one or more adjustable gangways. This type is used where the water level fluctuates considerably.

Two special wharf types are the mooring platform and the breasting platform. The mooring platform is a small offshore wharf with a square platform or deck. It provides berthage for a ship but is too small for cargo transfer. Mooring platforms commonly are provided in groups of two or more, and ships are berthed across the faces. One or more of a group of mooring platforms are generally connected with the shore by a narrow approach or trestle, and platforms may be connected by catwalks. The breasting platform is a small platform structure projecting from the face of the wharf bulkhead. Breasting platforms are usually provided in groups of two or more, and ships are berthed across the heads. See Figure 2-11.

An offshore pipeline berth is connected to the shore solely by a submarine or floating pipeline, which permits cargo transfer directly to storage installations on shore.

In a terminal buoy system, the terminal buoy looks similar to the standard mooring buoy but is substantially larger. It is positioned offshore in deep water with three or more chains attached to heavy anchors. The terminal buoy has a revolving platform or swivel to which the tanker is secured as are the floating hose lines for cargo, bunker oil, and fresh water. When the buoy's flexible hoses are coupled to the ship's system, this permits ship and hose lines to swing together a full 360 degrees with the wind or sea. Product transfer proceeds through submarine pipelines connecting the buoy and ashore installation.

Wharf construction and materials vary greatly; however, most structures are either open or solid construction. Open construction is used for marginal wharves, offshore wharves, and most piers. In its simplest and least permanent form, it consists of open-spaced wooden piling supporting a wooden deck. Variations designed to contribute to the strength and permanence of the open structures are

Figure 2-11. Types of wharf layout

numerous. Substructures may consist of steel or precast concrete piling. The superstructure or decking may vary from wooden joists and flooring to concrete and steel construction with an asphalt or other paved surface.

Solid construction is used in quays (and occasionally in piers) and consists of a solid backfill against a retaining wall and covered with a surfaced decking. Quay walls may be a simple facing of interlocking sheet steel piling, a monolithic concrete wall, or a masonry structure built of stone or precast concrete blocks. Many quays abroad consist of large concrete caissons sunk in line to form a wall, then filled with concrete or rubble and capped with a reinforced concrete deck.

Wharves require several basic dimensions; careful measurement and precise identification of reference points is essential. Measurement may be in either feet or meters, since conversion tables are available.

The length of one side of a pier may differ from that of the other, and both should be reported. The side of a pier or the face of a wharf may be irregular or stepped, and a dimension should be reported for each segment. Usable berthing space may or may not coincide with the overall length; shoals or other obstructions may decrease the usable length of a wharf.

The width of a marginal wharf may be difficult to determine, since the inner limit may not be defined. In such cases, the measurement points should be clearly identified. Width of apron is not to be confused with width of wharf. The apron is the working part of the wharf deck at shipside; it terminates at the transit shed or other obstruction.

The type and condition of the deck surface has an important bearing on the usability of a wharf. Analysts should indicate the layout of wharf railroad tracks with respect to the wharf deck. They should be particularly careful when reporting berthing capabilities of a wharf. Special or unusual berthing conditions include the breasting of ships off the wharf by means of pontoon, the presence of surge or swell that might require special mooring precautions, and draft limitations.

Harbor Craft

The operation of most ports requires a fleet of various harbor crafts. Although in large ports the composition of the fleet may undergo frequent changes, information about types, general numbers, and operating characteristics of harbor craft is essential.

Tugs are generally seagoing or harbor. Analysts should list the horsepower, power type, operating range of seagoing salvage tugs, and special equipment such as salvage or fire-fighting equipment. When no tugs are present, launches are important. They may be grouped by horsepower and power type.

Lighters may be broken down by size and type (self-propelled and dumb); in large ports their numbers may be given in round figures. Information requirements include such details as capacity, construction, power type, and specialized lighters for handling ammunition.

Harbor-dredging operations use dredges, hopper barges, and rock breakers. Dredges vary in type and mechanism, depending on the nature of the bottom

sediments to be worked. Hopper barges are self-propelled or dumb barges fitted with self-emptying hoppers. They haul material recovered by dredges. Rock breakers, as the name implies, are used in special cases when loosening of rock from the harbor floor is required.

Shipyards

Complete up-to-date information is required on shipyard facilities and on all firms capable of making marine repairs but lacking dry-dock facilities. Valuable information is contained in maps, yard plans, individual facility plans, shop layouts, photographs of yard facilities, and docking manuals. Each shipyard should be positively identified by position within a city or port, with references to outstanding landmarks on waterfront, rivers, and tributaries.

The principal types of dry-dock facilities are the graving dock, floating dry dock, and marine railway. The three gate types provided for graving docks are leaf gates, flap gates, and sliding caissons. Leaf gates are hinged swinging gates that fold back into recesses in the walls of the entrance when the dock is open. Flap gates are hinged at the bottom and lowered outward to a horizontal position in the approach to the dock. The sliding caisson rolls or slides on a track on the dock sill.

Ship construction and conversion are not treated in detail in port studies dealing with terrain intelligence; however, information about the physical facilities used in construction and repair are valuable to the intelligence analyst. This information includes the types of structural, engineering, electrical, and miscellaneous shops in which various shipbuilding and ship repair processes are performed; the types of ships constructed and the largest of each type constructed to date; whether repairs can be made without dry docking by means of caisson; the yard's reputation for speed in accomplishing repair work; and the general capabilities of the yard as to hull, engineering, and electrical repairs.

Naval Bases

Natural features required of a good naval-base site include a harbor with deep-water approaches; protected and spacious deep-water anchorages; positions capable of being easily defended; sufficient land for expansion; elevation of approximately 1.5 to 3 meters above mean high water at the waterfront; suitable ground for the foundation of dry docks, buildings, and heavy equipment; and an ample supply of safe, freshwater. Local labor, materials, and transportation must be adequate to support the operation. Secondary stations of the shore establishment are necessary to fleet operation.

Although they will vary in both size and relative importance, certain functional components are common to given types of naval bases. Submarine bases will almost always contain a torpedo shop, battery repair shop, electrical battery-charging equipment, and high-pressure air-charging equipment. Medical components of a large activity may contain, in addition to the normal medical and dental equipment, specialized equipment and resuscitating gear for divers. Analysts should indicate whether or not a particular component is included among the base installations.

Landings

Landings may be structures that are usable for landing, although primarily designed to serve some other function, or they may be beaches in the harbor on

which landings are possible. Landings assume particular importance when a port becomes unusable by damaged or sunken vessels and when they must serve as the supplemental or principal medium of transfer between ship and shore. These structures include breakwaters, sea walls, bulkheads, seaplane ramps, and beaching hardstands. In wall-type structures, the length, depth alongside as referred to chart data, height of the top above chart data, and batter of face wall are significant. For all structures, analysts should identify the construction type, condition of the sea and current alongside, and clearance facilities.

Airfields

Air facilities are the military and civilian installations upon which a nation's air operations depend. The fundamental air facilities are airfields, seaplane stations, and heliports. Each has its own facilities such as runways, hangars, fuel systems, maintenance ships, and crash, fire, and service equipment. At some small foreign airfields, many functions may be combined in one or two centrally located buildings.

A. Airfields:		
No.	Feature	Specifications
1.	Runways	Outline runways to scale.
2.	Taxiways	Outline taxiways connecting runways, aprons, and hardstands to scale.
3.	Aprons	Outline aprons to scale.
4.	Hardstands	Outline hardstands to scale.
5.	Airfield perimeter	Draw a boundary line representing the airfield perimeter.
6.	Structures	Outline all structures. Number each and list in the Data Table.
7.	Airfield name-elevation	Place name and elevation just outside the perimeter symbol.
8.	Runway azimuth	Place the runway azimuth at the end of the runway outline (within or just outside).
9.	Runway length and width	Place length and width designations inside, or just outside runway outline.
10.	Approach lighting	Show locations along line drawn to scale (length).
11.	Runways lights	Show locations by dot symbols along the lateral boundary of the runway.

Figure 2-12. Symbol specifications for airfields and heliports

B. Heliports:			
No.	Feature	Symbol	Specifications
1.	Landing area - runways		Draw outline of the landing area or runway to scale.
2.	Taxiways		Outline taxiways connecting runways/landing areas, aprons, and hardstands to scale.
3.	Aprons		Outline aprons to scale.
4.	Hardstands		Outline hardstands to scale.
5.	Heliport perimeter		Draw a boundary line representing the heliport perimeter.
6.	Structures*		Outline all structures. Number each, and list in Data Table.
7.	Heliport name/(No.) elevation	Columbus - 200m H-1	Place name (No.) and elevation just outside the perimeter symbol.
8.	Helipad (without facilities)		Circle .4" dia Letter .3" high

Figure 2-12 continued. Symbol specifications for airfields and heliports

The most advantageous location for an airfield is an area free from natural and cultural impediments to operations. An elevated rather than low area is preferred because of the absence of terrain obstructions and generally more favorable local weather conditions. Low areas are frequently exposed to adverse wind conditions, fog, and occasional flooding. Another important factor in airfield location is its intended use. Major civil airfields will almost always be located near the cities they serve. Major military installations, which normally require more land because of their vast complex of fixed facilities, are more often constructed some distance away from large cities. See Figure 2-12.

Auxiliary airfields are normally located near major operational or training bases. Often these facilities are on caretaker status during part of the year when their additional capacity is not needed.

A helipad is an area specifically designated and marked for helicopter landings and takeoffs. The surface of the pad may be natural, temporary, or permanent. A helistop refers to a helipad with little or no facilities and is used for on- and off-loading of cargo or passengers.

An airfield runway is a flat landing surface with a true or magnetic heading, normally taking advantage of prevailing winds. The number of runways or runs may vary from one to several, which are usually oriented in different directions. Some airfields have parallel runways (two runways with the same headings - not to be confused with a parallel taxiway). Runways are the most significant features of an airfield, and detailed information concerning them, taxiways, and parking areas is essential to properly evaluate the airfield's capabilities. The length, width,

load-bearing capabilities, and pavement condition directly influence the type and amount of traffic an airfield can accommodate.

Taxiways are access paths to parking aprons, hangar aprons, and handstands or revetments. A parallel taxiway parallels the runway but is usually narrower. Under emergency conditions it may be used as a runway, but it should not be reported as a runway. Link taxiways connect the runways with other taxiways, parking and hangar aprons, or revetments. A perimeter taxiway usually starts at one end of the runway and ends at the other, and is normally oval. Loop taxiways are normally located at or on both ends of the runway, forming a loop. The alert taxiway is located at the end of the runway with clear access to the runway for a scramble by fighter interceptors.

Runways, taxiways, aprons, and revetment surfaces may be permanent, temporary, or natural. Permanent surfaces such as concrete or asphalt have distinct edges and ends, while temporary surfaces such as mixed-in-place madam or oiled earth have ragged and uneven edges and ends. Permanently surfaced runways are easily discernible and may have jet barriers or arrester gear. Jet barriers are located on the overrun, whereas the arrester gear is normally flush with the runway and located approximately 500 meters from the end of the runway. This 500 meters is usable runway and should not be confused with an overrun.

Measuring permanent or temporary surfaced runways should not be difficult. The major difficulties are locating and arriving at the measurements of natural surface marked with painted barrels, reeks, or broken white lines. Runway lengths and surfaces vary according to the use or intended use of the airfield.

The weight- or load-bearing capacity of a runway, taxiway, or apron is a determining factor in its capability to accept aircraft without damage to the aircraft or the facility. The engineering factors involved in determining weight-bearing capacity are complicated; however, other sources for this information are route manuals, air information publications, airfield managers, and engineering documents. If these sources are not available, information about the type and weight of aircraft (partially or fully loaded) operating out of a given airfield will enable the analyst to estimate the weight-bearing capacity of the runway.

Natural Terrain

Chapter 3

SURFACE-CONFIGURATION OVERLAY

The surface-configuration overlay is used to depict the inclined surface of the terrain and is expressed using percent of slope or change of elevation (rise) divided by the horizontal distance (run).

This overlay is one of the primary overlays used in determining the cross-country movement capability of troops and vehicles.

A 1:50,000 topographic map is required to construct a surface-configuration overlay using TTADB product specifications.

Step 1. Examine topographic maps. Construct a surface-configuration overlay for the TTADB using a standard 1:50,000 topographic map with a variety of possible contour intervals. A contour interval of 20 feet or less is preferred for constructing this overlay.

Register the overlay to the database or map you are using. Cover the selected topographic map with a clean sheet of mylar and tape them together. If the area of interest does not cover the entire map, outline the area of interest on the mylar in black pencil or ink and note the longitude and latitude or UTM coordinates at the corners.

Annotate the map sheet name and number, map series, map edition, scale, contour interval, factor overlay type (surface configuration) and classification, if required, on the overlay.

Step 2. Depict surface-drainage features. Trace the boundaries, in black pencil or ink, of all islands longer and wider than 250 meters (5 millimeters at the scale of 1:50,000). Show long, narrow islands (those less than 250 meters wide) only if they are greater than or equal to 1000 meters in length (20 millimeters on the map).

Trace the boundaries of all open-water bodies such as ponds, lakes, reservoirs, and double-lined streams in black pencil or ink. Label all open water with a **W**.

Step 3. Depict dissected terrain. Trace the boundaries of all naturally and/or culturally dissected land areas in black pencil or ink and label with a **G**. Dissected terrain includes, but is not limited to, pits, quarries, dumps, landfills, piles, ravines, and gorges. Many of these features are easily recognized on topographic maps.

Step 4. Outline and label slope categories. Select a slope calculator (See Figure 3-1.) that was constructed for the scale and contour interval of the map used. A slope calculator, also called a template or wedge, is an instrument for measuring the percent of slope on a topographic map. This instrument is constructed of a transparent, stable-base material and is marked with predetermined distances that correspond to the desired slope category. Ensure the slope calculator has the required slope categories established within the TTADB product specifications. If a suitable slope calculator is not available, you must construct one for the map you are using.

Example: Construct a slope calculator for slope categories of 0-3 percent and 3-10 percent, given a 1:50,000 topographic map with a contour interval of 20 meters.

a. Determine the horizontal distance required, with an elevation difference (contour interval) of 20 meters to equal the largest slope percent of a given category.

$$HD = \frac{CI \times (100)}{\% \text{ slope}}$$

HD = horizontal distance

CI = contour interval

% slope = largest slope percent of a given category

(100) = constant

Formula: Slope category A (0 to 3%)

$$HD = \frac{20 \times (100)}{3}$$

Figure 3-1.

Hd = 666.6 meters (CI was in meters)

Formula: Slope category B (3 to 10%)

$$HD = \frac{20}{10} \times (100)$$

HD = 200 meters

b. Determine the map distance, or the spacing of the contour intervals, required to construct the slope calculator for categories **A** and **B**:

$$MD = \frac{HD}{D}$$

MD = map distance

HD = horizontal distance (from previous formula)

D = denominator of map scale

Slope Category A (0-3%)

$$MD = \frac{666.6}{50,000}$$

MD = .01333 meters or (13.33 mm)

Slope Category B (3-10%)

$$MD = \frac{200}{50,000}$$

MD = .004 meters or (4 mm)

Note: You must calculate map distances for each slope category outlined in TTADB product specification (PS/3JB/020) and for any slope category required for a special-purpose product.

c. Construct the slope calculator. Construct the slope calculator using the map distance calculated from the above formulas on a clear, stable-based material. Draw several ticks representing the same slope category.

d. Outline the slope categories. Analyze the contour lines on a topographic map using the slope calculator to outline and label slope categories. Slope categories are areas on a map where the slope is the same or is in the same category.

Start the slope analysis in the upper left-hand corner of the map and determine map areas whose slope (contour interval) matches the 0 to 3 percent (or lowest category required) slope category on the calculator (See Figure 3-2). When you have outlined all areas within this category using a black pencil or ink, label all outlined areas with an A or representative symbol from your legend.

Continue this analysis for all slope categories that you have outlined and labeled. Prepare the surface-configuration legend according to TTADB product specifications.

Figure 3-2. Slope example

Step 5. Determine slope from aerial photography. Determining slope from aerial photography requires complete stereo coverage. It is time-consuming and requires more skill than using a topographic map. You should use this method only if topographic maps are not available or if you need precise slope measurements from a point to a point. You cannot use this process to compile a surface-configuration factor overlay, since this overlay is keyed to a topographic base map.

Step 6. Construct the final overlay. The final step in producing a factor overlay is to put the draft manuscript overlay into a final database product. You must have support from the cartographic and reproduction elements or sections. See Chapter 8 for the final overlay procedure.

VEGETATION OVERLAY

The vegetation overlay shows natural and cultivated vegetated areas, with information about type, size, and density. This factor overlay is one of the primary overlays used in determining the cross-country movement capability of troops and equipment, cover and concealment line of sight, and location of construction resources.

A 1:50,000 topographic map and complete stereo imagery is required to construct a vegetation factor overlay using TTADB product specifications.

Step 1. Collect required collateral data. The vegetation factor overlay is one of the most complex and difficult factor overlays terrain analysts construct. No single source data can provide all of the data required to complete the vegetation factor overlay and data tables. In most cases, analysts must use different sources for different geographic areas. Unlike other factor overlays, where terrain factors are similar worldwide, geographical location, climate, soils, and the agricultural practices of the location being analyzed greatly influence the vegetation factors. Some of the major sources are maps, literature, and aerial imagery.

Military topographic maps. Standard military topographic maps differ in completeness according to scale and country of origin. The boundaries of forested areas

are generally accurate on topographic maps but size, type, and density information cannot be obtained from the map alone. See Figure 3-3.

Small-scale vegetation maps. This product can be found in any general geography text and usually depicts very broad categories of vegetation. It does not give enough of the detailed information required but will give analysts background on agricultural practices and the predominant vegetation types of the area.

Data Element	United States		Federal Republic Germany		USSR	
	1:250,000	1:50,000	1:250,000	1:50,000	1:200,000	1:50,000

12. Mean height to lowest branches	No	No	No	No	Limited	Limited
13. A representative transect	No	No	No	No	No	No

Figure 3-3. Map capabilities for vegetation data elements

Species distribution maps. These maps are produced under a variety of names depending on their geographical location and the type of data they present. They are produced primarily for use as forestry tools by government agencies, commercial lumber companies, and colleges and universities. They provide extremely detailed information but are produced for limited areas and specific functions. If they are not available, the analyst should query local government agencies and universities located in the area of interest. This is only feasible if the area of interest is accessible to the terrain analyst and if local agencies are friendly and willing to assist.

Literature. Literature is nearly unlimited in quantity, scope of subject matter, and coverage of geographic regions. Data from this source is usually too general to be of much use but can be used to verify other data.

Aerial imagery. Analysis of aerial imagery is the best and most accurate method of obtaining detailed vegetation information. The quality of information obtained depends largely on the skill and knowledge of the individual analyst and the type and quality of the imagery available.

Step 2. Determine data elements. After identifying and collecting sources of information, analysts must determine the data elements or essential elements of

terrain information (EETI) required to produce the vegetation factor overlay. The data elements required are--

- Vegetation-area boundaries.
- Vegetation type.
- Height to top of canopy.
- Canopy closure.
- Stems per hectare.
- Stem diameter.
- Stem spacing.
- Ground cover.
- Height to lowest branches.
- Seasonal information.

Step 3. Prepare collateral data. Gather all available data that covers the area of interest. Examine the information to ensure completeness and accuracy, to see if some of the information is old or dated, and to see if newer sources are available. Vegetation can be influenced by man's activities and can change in a relatively short period of time.

Identify information gaps. After all available information has been gathered, superimpose it on the base map to determine areas where information does not exist or is too old to be reliable.

Submit collection requirement. If information gaps exist, determine alternate available sources and submit the appropriate collection requirement. The collection request can be for new imagery or for on-site verification of dated information.

Step 4. Prepare topographic map base. Construct the vegetation overlay for the TTADB using a standard 1:50,000 topographic map. Register the overlay to the data base or map you are using. Cover the selected topographic map with a clean sheet of mylar and tape them together. If the area of interest does not cover the entire map, outline the area of interest on the mylar in black pencil or ink and note the longitude and latitude or UTM coordinates at the corners. Annotate the map sheet name and number, map series, map edition, state, factor overlay type (vegetation) and classification, if required, on the overlay.

Prepare the data table worksheets. Trace the boundaries, in black pencil or ink, of all open-water bodies such as ponds, lakes and double-lined streams and label them with a **W**.

Trace the boundaries of all built-up areas that are longer and wider than 250 meters (5 millimeters at 1:50,000 scale). Label the outlined areas with an **X**.

Step 5. Determine vegetation types and boundaries. Trace the boundaries of all forested areas. For the working overlay, label all forested areas with a **T**. Further analysis will determine type, size, density, and internal boundaries or changes.

Trace the boundaries of all agricultural areas and label the areas with an **A**. Determine the type of crops, such as dry, wet, terraced or rotating/shifting crops and add the second agricultural code (see Figure 3-4.). The analysis of collateral data will be required to determine the second code.

Trace the boundaries of all brushlands and label them with a **B1** or **B2**, depending on the vegetation category. The analysis of collateral data will be required to determine the second code.

MAP UNIT CODE	TYPE
A1	Agriculture (dry crops)
A2	Agriculture (wet crops, rice)
A3	Agriculture (terraced crops, both wet & dry)
A4	Agriculture (shifting cultivation)
B1	Brushland (< 5m high, open to medium spacing)
B2	Brushland (< 5m high, medium to dense spacing)
C*	Coniferous/Evergreen Forest
D*	Deciduous Forest
E*	Mixed Forest (Coniferous/Deciduous)
F*	Orchard/Plantation (rubber, palm, fruit, etc.)
G1	Grassland, Pasture, Meadow
G2	Grassland with Scattered Trees, some Scrub Growth
H	Forest Clearing (cutover areas, burns, etc.)
I**	Swamp (mangrove, cypress, etc.)
J	Marsh/Bog (treeless bogs, muskegs, etc.)
K	Wetlands (L.S.L., low-lying wet areas)
L	Vineyards/Hops
M	Bamboo
N	Bare Ground
W	Open Water
X	Built-up Area

*These vegetation types are given a three digit map unit code. In addition to the letter for the type code, a second digit (number) is added as the canopy closure code, and a third digit (number) is added as the height code. See Canopy Closure (%), Height (meters), and example below.

** A second digit, representing canopy closure, is added to the swamp code.

Figure 3-4. Vegetation map codes

Trace the boundaries of all grasslands and label them with a **G1** or **G2**, depending on the vegetation category. The analysis of collateral data will be required to determine the second code.

Trace the boundaries of all swamps (**I**), marshes and bogs (**J**), and wetlands (**K**) and label them accordingly.

Step 6. Determine forest type and boundaries. Since different types of trees have different characteristics and have a major impact on cross-country mobility, on cover and concealment, and on use as engineering resources, you must determine the forest type and the transition boundary of the areas already labeled **T**.

Trace the boundary of all coniferous/evergreen forests and label them with a **C**. This forest category must contain 60 percent or more species of coniferous trees. These trees are relatively easy to place within a broad classification because they tend to have definite sizes and shapes. Shadows, crown shape (see Figures 3-5 and 3-6) and photographic tone are the most common photo interpretation keys.

Trace the boundaries of all deciduous forests and label them with a **D**. This forest category must contain 60 percent or more species of deciduous trees.

Trace the boundaries of all mixed forests and label them with an **E**. Mixed forests are those forests that do not contain 60 percent or more of either coniferous or deciduous trees.

Figure 3-5. Vertical views of tree crowns

Trace the boundaries of all orchards and/or plantations and label them with a **F**. This category can be identified by the uniform rows and photographic tone and texture. Analysis of the collateral data will key analysts to look for this vegetation type and location.

Step 7. Determine canopy closure. Canopy closure is the percent of ground area covered by the tree crown and is normally computed only for forested areas. Crown area is the area covered by the vertical projection of a tree crown to the horizontal plane.

Vegetation types indicated by **C**, **D**, **E** and **F** are given two digits in addition to the letter. The letter denotes the tree type, the first number represents the canopy closure, and the second number is the height. For swamps (**I**), the third digit or height code is omitted.

Canopy closure is coded in four categories:

CODE	CANOPY CLOSURE %
1	0 - 25
2	25 - 50
3	50 - 75
4	75 - 100

Use the crown density scale to determine the canopy closure. It is made of columns of squares containing solid black circles. These circles cover and represent a percent of the area (see Figure 3-7 within the square). Match the appropriate scale to the forested area on the imagery and record the crown density for a given area.

Figure 3-6. Silhouettes of forest trees.

Compare only the tree crown and not the shadows visible on the photo. Factors affecting accuracy of canopy closure measurements include--

Note: When tree shadows fall on level ground, they often permit identification of individual species.

Figure 3-7. Sample crown density scale

- Image quality. Crown closure estimates of forest stands on poor quality photographs tend to be too high because of the lack of detail in photo tones and the inability of the analyst to identify small crown openings.
- Shadows. Shadows tend to mask stand openings causing the stand to appear more dense.
- Photographic scale. The minimum canopy opening that can be identified on photography is directly related to the photographic scale. Small openings which can be identified on 1:6000 scale photography cannot be seen on 1:20,000 scale photography. The net effect is to overestimate canopy closure when using small-scale photography.
- Analyst skill. An average analyst using good quality photography should produce crown closure estimates accurately to within 10 percent.

Step 8. Determine the mean height to top of canopy. The second number, or third digit, depicts the tree height (see Figure 3-8). Mean height to top of canopy is the mean or average height of a specific tree type or category. If existing data to determine and outline mean tree height does not exist, use aerial photography to measure tree height (see Chapter 9). Three methods to measure tree height from aerial photography are the parallax, shadow, and relief displacement methods. Factors affecting the accuracy of height measurements include--

- Photographic scale. Tree height measurement error generally increases when small-scale photography is used due to the inability of the analyst to identify the tree's apex.
- Character of forest. Measurement of tree height is dependent on the analyst's ability to see the ground nearby. This is closely related to the stand density and ground clearance. If a forest stand is very dense, such as a tropical rain forest, it is very difficult to find an opening large enough to permit accurate measurements.

Figure 3-8. Tree mensuration

- Terrain relief. Trees growing in areas that are not level are difficult to measure accurately because of a tendency to refer measurements to canopy openings at elevations different than those at the base of the tree.
- Analyst skill. An analyst should be able to determine the height of trees accurately within each map unit. Knowledge of forest conditions and classification of specific tree type (species) can be an invaluable aid in height classification.

Step 9. Determine tree crown diameter. Tree crown diameter is the distance across the spread of a tree crown and is measured in meters. Diameter measurements of the largest, average, and smallest crowns in each category will determine the average crown diameter for a given map unit. This measurement is made using the dot-type scale or the crown micrometer wedge on the photograph (see Figure 3-9).

Select a tree for measurement. Slide the dot-type scale alongside the tree until you find a dot that is equal in size to the tree's crown. It is best not to fit the circle over the crown, because too much detail is screened by the black dot or circle.

Figure 3-9. Crown micrometer wedge

Select a tree for measurement. Place the micrometer wedge so the insides of the two diverging lines are just tangent (making contact at a single point) to the tree. Take a reading at the point on the scale where the tree crown is tangent to the diverging lines.

Take an average of three measurements using either method. The answer will be in millimeters of photo distance. Convert the answer to ground distance by multiplying by the denominator of the photo scale. Convert millimeters of ground distance to meters by dividing by 1000. Factors affecting accuracy of crown diameter measurement include--

- Photographic scale. The analyst's ability to accurately identify the largest, average and smallest crowns is closely associated with the photographic scale. Small-diameter crowns cannot be detected on small-scale photographs, and clumps of closely spaced trees tend to be measured as a single crown rather than as several small ones.
- Location on the photograph. Limit tree crown measurements to the center portion of the photograph whenever possible, because the center is less affected by distortion.
- Forest density. Crown diameter measurements are most accurate in open-grown stands. Measurements in dense stands are usually limited to crown widths for dominant trees.

Step 10. Determine mean stem diameter. Tree stem diameter is the diameter of a tree at 1.4 meters (4.5 feet) above the ground. This measurement is also referred to as diameter at breast height (DBH). Calculate mean stem diameter for all vegetation units with trees 2 meters or greater in height. Record this information on the vegetation data table in centimeters.

Tree stem diameter is calculated using the mean crown diameter information obtained in step 9. If this step has not been completed, calculate the mean crown diameter for the vegetation within each map category.

When computing the stem diameter for coniferous trees, use the following formula:

$$\text{DBH (inches)} = \frac{\text{D (feet)}}{2} + 5$$

Where--

DBH (inches) = Diameter at breast height

D (feet) = Crown diameter

Example: In step 9, you have determined that a stand of coniferous trees has a mean crown diameter of 6.4 meters.

a. Convert mean crown diameter measurement to feet.

$$6.4 \text{ meters} \times 3.281 \text{ feet per meter} = 20.998 \text{ feet}$$

(Round to 21 feet)

- b. Use the above formula to determine DBH (inches).

$$\text{DBH} = \frac{21 \text{ feet}}{2} + 5 \quad \text{DBH} = 15.5 \text{ inches}$$

- c. Convert DBH (inches) to centimeters.

$$15.5 \text{ inches} \times 2.54 \text{ inches per cm} = 39.37 \text{ cm}$$

- d. Record the mean stem diameter in the vegetation table.

When computing the stem diameter for deciduous trees, use the following formula:

$$\text{DBH (inches)} = .75 \times D \text{ (feet)}$$

Example: In step 9, you have determined that a stand of deciduous trees has a mean crown diameter of 8.5 meters.

- a. Convert mean crown diameter measurement to feet.

$$8.5 \text{ meters} \times 3.281 \text{ feet per meter} = 27.885 \text{ feet}$$

(Round to 27.9 feet)

- b. Use the above formula to determine DBH (inches).

$$\begin{aligned} \text{DBH} &= .75 \times 27.9 \\ \text{DBH} &= 20.925 \text{ inches} \end{aligned}$$

- c. Convert DBH (inches) to centimeters.

$$20.925 \text{ inches} \times 2.54 \text{ inches per cm} = 53.1495 \text{ cm}$$

Round the answer to 53.15 cm.

- d. Record the mean stem diameter in the vegetation table (see Figure 3-10)

Step 11. Determine stem spacing. Stem spacing is the distance from the center of one tree to the center of the nearest adjacent tree. The easiest and fastest method to determine stem spacing is to measure directly from the photograph and convert it to ground distance (in meters).

Use the microcomparator to measure from the center of a tree stem to the center of the closest tree stem. This measurement unit depends on the scale used in the microcomparator, usually made in feet, and should be converted to meters.

If the scale is not acceptable and the distance is not measurable, use the following formula:

$$\text{SS (meters)} = \frac{12.372}{N}$$

CODE	FOREST TYPE AND CANOPY CLOSURE															
	C1	C2	C3	C4	D1	D2	D3	D4	E1	E2	E3	E4	F1	F2	F3	F4

3						5.0 1.8 .80										
H E I G H T																
4																
5																
6																
7																
8																
9																

Example D23 indicates the following: 5.0 cm — Average Stem Diameter
1.8 m — Average Tree Spacing
.80 — Vegetation Roughness

Figure 3-10. Vegetation table

Where--

SS (meters) = Stem Spacing in meters

12,372 = Constant

N = Number of trees per hectare

Before you can use this formula, you must determine N. To determine N, use the following formula:

$$N = \frac{\text{TC (tree count in hectare scale)}}{0.08}$$

N = Number of trees per hectare

TC = Tree count in hectare scale

Determine TC (tree count in hectare scale) of a specific vegetation map code. Orient the stereopair for viewing. Place the transparent 0.08 hectare scale (see Figure 3-11) over the area using the appropriate photographic scale and count the number of trees enclosed within the circle of the hectare scale.

Convert the number of trees in a 0.08 hectare to the number of trees per hectare.

Example: 32 trees were counted within the 0.08 hectare circle using the 0.08 hectare circle template.

a. Use the above formula to determine N.

PHOTO SCALE	.08 HECTARE CIRCLE	CIRCLE DIAMETER	
		INCHES	MILLIMETERS
1:5,000		.253	6.38
1:6,000		.211	5.32
1:7,000		.1805	4.56

X	(not evaluated)

Figure 3-12. Vegetation roughness factors

c. Round off to the nearest 0.1 meter and record this figure in the appropriate column of the vegetation data table. Factors affecting accuracy of stem spacing measurement include--

- Tree spacing. Count only those trees that are visible from above and are sufficiently large in their exposed portion to be resolved. This problem is especially acute in tropical areas having more than one canopy.
- Photographic scale. Trees with a crown diameter of less than 0.6 meters will not be resolved at 1:12,000 scale photography. This minimum-resolved diameter increases to 1.2 meters on photo of 1:16,000 scale or smaller.
- Tree crown diameter. Tree count accuracy increases with an increase in tree crown diameter.
- Crown canopy structure. Irregularities in crown canopy tend to increase accuracy due to relief among trees.
- Terrain. If the terrain viewed in the photograph is not level, alter the area represented by a given circle or adjust the crown count to obtain the true number of trees per hectare. Compute compensation for terrain relief for every 200-foot difference in elevation.
- Analyst's skill. Inexperienced analysts may undercount the actual number of tree crowns by as much as 50 percent. For this reason, you must be careful to recognize double trees, sprout clumps, or multiple groups of trees. You can usually accomplish this by recognizing abnormally large crowns or irregularly shaped groups of crowns.

Step 12. Estimate vegetation roughness factor (VRF). The vegetation roughness factor is an estimated numerical factor that reflects the degree of vehicular speed degradation due to travel through a particular vegetation type on horizontal ground. The factor decreases from 1.0 (no speed degradation) to 0.00 (vegetation roughness does not permit off-road mobility) (see Figure 3-12). For example, grassland with little slowdown effect would have a VRF of 1.0 to 0.9, but a virtually impassable swamp with dense ground vegetation, fallen branches and trees, and exposed stumps would have a VRF of .1. The factor designated to a vegetation category is subjective and designated by the analyst. The plant's density, stem diameter, branching characteristics, root emergence, and so forth are all considered.

Step 13. Prepare the vegetation legend. Prepare the vegetation factor overlay legend according to DMA product specifications.

Step 14. Construct the final overlay. The final step in producing a factor overlay is to put the draft manuscript overlay into a final data base product. Support from the cartographic and reproduction elements/sections is required. See Chapter 8 for the final overlay procedure.

SURFACE MATERIALS ANALYSIS (SOILS)

Military planners rely heavily on soil analysis because soils vary in their ability to bear weight and withstand vehicle passes, as well as in their ease of digging. The moisture content and type of soil will affect road construction, material location, and trafficability determination. The soil factor overlay breaks down the soil types, characteristics, and distribution. Soils of the same type and quality will have similar strength and characteristics regardless of geographic location. The primary factors influencing like soil strengths are environmental changes.

Describing and classifying soil normally requires extensive field sampling and the expertise of soil scientists. The terrain analyst must be able to produce acceptable soil factor overlays by extracting information from maps, other factor overlays, aerial photographs, lab reports, boring logs, and other literature. The reliability of the soil factor overlay produced will vary with the type and reliability of the information sources. Seldom will a single source provide all of the information required.

Step 1. Collect required collateral data. Collect and analyze as many of the following sources as possible for the area of interest; maps; factor overlays; special reports, such as laboratory soil analysis reports, soil field test reports, and boring logs and well logs; literature; and aerial photographs.

The desirable scale for all source maps is 1:50,000. If 1:50,000 scale maps are not available, other existing maps should be converted to this scale.

Soil maps are produced by various organizations for specific purposes. Engineering firms may produce soil maps to support any type of construction project. Government agencies may produce soil maps for agricultural purposes, land-use planning, or special studies. The classification systems used on soil maps will vary with the producing agency and the purpose of the map. The systems must be translated into the USCS, which is the system used by the military for producing soil factor overlays. See Figure 3-13.

This table may be used as a guide in classifying soils for which no engineering test data are available. The symbol > means "greater than", the symbol < means "less than", and the symbol ≤ means "less than or equal to".

Figure 3-13. General relationship of systems used for classifying soil samples

Some vegetation features symbolized on topographic maps can provide clues to soil characteristics. Contours and land-use patterns can help define landforms and identify soil types. See Figure 3-14.

Geological maps may or may not be useful form soil analysis. Those maps which show the surface profile to bedrock usually define the type and depth of soil, as well as the parent material or bedrock.

In some cases, vegetation (or change of vegetation) can be an indicator of a specific soil type, change of soil type, or change of soil depth.

Climatic maps provide annual variations in temperature and moisture conditions. Of particular interest is information concerning the state of ground; for example, wet, dry, moist or frozen. This information is important in determining the stability of a soil or changes of stability with seasonal changes.

Literature reports are published by academic institutions, government agencies, or private firms on soil-related subjects such as soil, topography, geology, and vegetation.

Analysis of air photographs is the best overall method for obtaining soil information for large and inaccessible areas.

Step 2. Determine data elements. Once you have identified and collected the sources of information, determine the data elements, or EETI, required to produce the soils factor overlay. The data elements required are--

- The soil profile, which is a description of the soil with depth, including identification of soil layers; depth ranges for each horizon layer in

meters; and identification of soil type for each horizon with one of the 15 USCS symbols.

- Depth to bedrock, or the total thickness of soil in meters.
- State-of-ground, or the average monthly moisture condition of the soil.
- Stoniness, or the estimated number of stones of a given diameter per volume of soil, which may be expressed as a percentage of the volume.
- The rating cone index (RCI), an on-site or estimated value of soil strength derived from the cone index multiplied by the remolding index.
- The cone index (CI), the field measurement indicating the shearing resistance of soil, obtained with a cone penetrometer.

- The remolding index (RI), a ratio that expresses the proportion of original strength that will be retained by a fine-grained soil or a sand with fines, poorly drained, after being subjected to vehicular traffic.

Step 3. Prepare collateral data. Gather all available soil maps that cover the area of interest. Examine their scales and legends. Extract those at 1:50,000 scale or larger that use the USCS. If any of these maps are based on field surveys (field classification), they may be used as the soil factor overlay base. Further data analysis or extraction may be unnecessary if the soil maps can produce all the information required by the data elements.

Step 4. Prepare topographic map base. Extract the topographic maps that cover the area of interest. A scale of 1:50,000 with a contour interval of 20 feet or more is preferred.

Cover the selected topographic map with a clean sheet of mylar and tape them together. If the area of interest does not cover the entire map area, outline the area of interest on the mylar in black pencil or ink and note the longitude and latitude or UTM coordinates at the corners. Register the overlay to the data base or map you are using.

Annotate the map sheet name and number, map series, map edition, scale, factor overlay type (surface materials) and classification, if required, on the overlay.

Trace the boundaries of all open-water bodies such as lakes, ponds, and double-line streams in black pencil or ink, and label them with a W.

Trace the boundaries of all built-up areas that are longer than 250 meters (5 millimeters at 1:50,000 scale). Label the outlined areas with an X.

Trace the boundaries of all permanent snowfields in black pencil or ink, and label with a them PS.

Trace the boundaries of all areas of salt evaporators and salt encrustation in black pencil or ink, and label them with an EV.

Step 5. Determine soil types and boundaries. Evaluate collateral source material for soil boundaries and types. If data does not already exist, analyze landforms, vegetation, and geology information to determine USCS type and boundary.

Trace the boundaries of all areas of exposed bedrock or void of surface soils in black pencil or ink, and label them with an RK.

Evaluate the soil factors and place appropriate boundaries on the overlay in black pencil or ink, using the topographic map as a base.

Label all evaluated areas with the appropriate USCS symbol. If information conflicts exist between different source materials, use the most reliable and current information available. Assign to each different area (soil type) a map unit number, numbering from top to bottom and left to right. Areas with the same surface soil type and identical horizon information will have the same map unit number. Do not assign map unit numbers to RK, PS, EV, X and W areas. The third digit after the USCS symbol shows the surface roughness factor.

Figure 3-15. Sample data table

Step 6. Determine surface roughness. Surface roughness factors are estimated factors used to compute the degree of degradation of the rate of vehicle movement caused by surface characteristics. These factors are tailored for each job by listing only those features encountered. Surface roughness is that aspect of the surface materials (such as boulder fields, gullies, and rugged bedrock.) which reduces vehicle speed.

Factors can be any number from 0.00 to 1.00 in 0.05 increments. The surface roughness factor of 1.00 for a vehicle class would indicate no degradation while a 0.80 factor would degrade vehicle speed by 20 percent. In estimating the magnitude of the factor, consider all physical characteristics of the feature as well as vehicle characteristics such as ground clearance and wheel size.

Surface roughness is classified for five types of movement categories: medium and large tanks, large wheeled vehicles, small wheeled vehicles, small tracked vehicles, and foot troops. Surface roughness factors often vary from one vehicle class to another.

Step 7. Prepare surface materials legend. Prepare a soil data table with RCI values for wet and dry seasons (see Figure 3-15). Using all available information, annotate the data elements required to complete the soil data table. This information can be used to increase the database for an area of operations.

Prepare the surface materials legend. The legend will contain only USCS soil categories with the appropriate surface roughness information. Depict additional information, such as soil depths and soil moisture from the soil data table, in the legend and within the factor overlay.

Step 8. Construct the final overlay. The final step in producing a factor overlay is to put the draft manuscript overlay into a final data-base product. Support from the cartographic and reproduction elements or sections is required. See Chapter 8 for the final overlay procedures.

OBSTACLE OVERLAY

The obstacle overlay is used to show the location and type of linear obstacles to movement. These obstacles can be either man-made or natural. This factor overlay is used with other primary factor overlays to produce cross-country mobility products and to assist military planners in developing barrier plans to tie planned obstacles into existing obstacles.

A 1:50,000 topographic map and complete stereo imagery are required to construct an obstacle factor overlay using TTADB product specifications.

Step 1. Collect required collateral data. Some of the major sources for data are maps and aerial imagery.

Standard military maps differ incompleteness and accuracy according to scale, currency and country of origin. Most existing obstacles are shown on topographic maps and can be plotted by the analyst.

Large-scale city maps can be used to plot the obstacles in and around built-up areas. The United States Geological survey (USGS) produced 1:24,000 maps show more detail than smaller scale maps. Use them as source material if they exist in your area.

Analysis of aerial imagery is the best and most accurate method of beating and plotting obstacles. Most natural obstacles, such as escarpments and embankments, are not high enough to be shown by the contour interval of a map, but they can be identified using aerial photos. Use imagery to locate and identify fences, walls, and hedgerows, which are not usually shown on standard maps.

Step 2. Prepare topographic map base. Register the overlay to the database or map you are using. Cover the selected topographic map with a clean sheet of mylar and tape them together. If the area of interest does not cover the entire map, outline the area of interest on the mylar in black pencil or ink. Mark and label the longitude and latitude or UTM coordinates of the corners.

Step 3. Identify and plot existing obstacles. Identify and plot all road and railroad cuts and fills greater than 250 meters in length and 1.5 meters in height. Start by following all of the ground lines of communication and look for areas where the terrain was altered to build a stable road or railroad. Railroads will normally have more cuts and fills to maintain a relatively flat gradient. Photo-check the cuts and falls plotted from the map and look for roads or railroads not shown on the maps. Plot the cuts and fills according to TTADB product specifications.

Identify and plot escarpments and embankments greater than 250 meters long and 1.5 meters high. Start by following all streams and rivers and look for areas where the contour lines converge. Look for areas where flat terrain transitions into more rugged, steep terrain. Photo-check these areas and mark the areas where escarpments, embankments, cliffs, ravines, and old stream banks exceed 45 percent. Plot the obstacles using the appropriate symbols.

Identify and plot depressions. Check geologic formations to determine if natural depressions are present. Sinkholes are commonly found in areas containing flat-lying limestones (karst topography) with historically wet climates. Topographic maps show most large depressions. Photo-check these areas and look for new pits, quarries, and open-pit mines. Plot all depressions which are greater than 250 meters long and 1.5 meters high and have slopes greater than 45 percent with the appropriate symbol.

Identify and plot other man-made features and any unique feature which can be classified as obstacles.

Step 4. Prepare the obstacle legend. Prepare the obstacle factor overlay legend according to DMA product specifications.

Step 5. Construct the final overlay. The final step in producing a factor overlay is to put the draft manuscript overlay into a final data-base product. You must have support from the cartographic and reproduction elements or sections. See Chapter 8 for the final overlay procedures.

Man-made Features

Chapter 4

Transportation Identification

Using a 1:50,000 scale map of the area, register the mylar to the base map and annotate the marginal information.

Roads

Step 1. Use the legend of the base map to locate the road classification and type of route. The route identification numbers will be located astride each road inside the route symbol. In some areas where the local government does not assign the roads identification (ID) numbers, you will need to assign arbitrary numbers.

Step 2. Trace all road segments onto the overlay using the proper symbol for each road classification. While tracing each road, look for points where either the classification or ID numbers change. Place a mute symbol at each point of change and annotate the classification and ID numbers as needed. As you trace each road, consider that interstate and federal routes do not change when crossing state or county boundaries. State roads change both classification and ID numbers when crossing state boundaries, and county roads either change classification or are terminated when crossing county or state boundaries. See Figure 4-1.

Step 3. Carefully study the base map legend and compare it the 1:50,000 (TTADB) and 1:250,000 (PTADB) product specifications to determine which factor overlay symbol to use for each map symbol.

Step 4. The surface material of each road is located in the legend across from the appropriate classification symbol. Determine which base map symbol is used in making the factor overlay and record the feature for each symbol in the legend of the factor overlay.

Step 5. Determine the width of the traveled way. Your accuracy in this will vary with the topographic map available. The FRG, USSR, and other European maps indicate the width in meters, but US maps indicate it by the number of lanes or a range of widths. Each road segment between intersections is assigned a width

SYMBOL	HIGHWAYS
	All weather, dual highway
	All weather, hard surface
	All weather, loose surface
	Fair weather, loose surface
	Cart tracks
	Width in meters (Δ denotes travelled way width change)
	Constriction (width in meters)
	Grade > 7%
	Sharp curve (radius < 30 meters)
	Ferry
	On route ford
	Feature under construction
	Bridge or tunnel (≥ 100m length)

Note: Only a representative pattern of major through routes and secondary roads are annotated.

Figure 4-1. Transportation legend (highways)

value, with that number placed parallel to the road segment. Table 4-1 below indicates lane widths currently shown on US military maps.

	Meters	Feet
Trail	Less than 1.5	Less than 5
Track	At least 1.5 but less than 2.5	At least 5 but less than 8
One lane	At least 2.5 but less than 5.5	At least 8 but less than 18
Two lanes	At least 5.5 but less than 8.2	At least 18 but less than 28
More than two lanes	At least 8.2	At least 28

Table 4-1. Lane widths currently shown on US military maps

Follow each route and determine the number of lanes and widths. Convert the lane width to meters to indicate the minimum width of the traveled way. Lightly record this value along the road outlined on the overlay.

Always use a decimal point when recording the road width, for example, 5 meters = 5.0 meters. Assign each road segment between intersections a width value, then place that number on the road segment. Note every point at which a change in width occurs and place a segment symbol at each of those points.

When dual routes occur, indicate the width of each route. If the source map gives only the overall width, assume each side has half the width.

Step 6. Depict gradient or percent of slope on the overlay when it exceeds 7 percent. The flat end of the first arrowhead is at the bottom of the grade, and the point of the last arrowhead is at the top. Measure the gradient from the topographic base map.

To determine percent of slope, measure the change in elevation (vertical distance or rise) and divide it by the horizontal distance (run), then multiply by 100.

$$\frac{\text{Rise} \times 100}{\text{Run}} = \text{percent slope}$$

Step 7. Show a constriction when the road narrows to less than 4 meters. Indicate the width measurement adjacent to the arrowhead symbol.

Step 8. Record all sharp curves with a radius of 30 meters or less.

Step 9. Depict all features that are currently under construction with the circled symbol *UC*.

Step 10. UTM coordinates are given for key reference points and features. See FM 21-26, which discusses map-reading instructions.

Bridges, Tunnels, Galleries, and Snowsheds

Step 1. All bridges are not usually drawn to their true scale on US military maps. Bridges less than 100 meters long are shown as point features, and bridges greater than or equal to 100 meters are symbolized by wing ticks. The only bridges not shown are located on roads that are not depicted. Plot the length between wing ticks to scale; minimum length between wing ticks is 2.0 millimeters. Point features are less than or equal to 2.0 millimeters. Draw all other features to scale.

To determine the true length of a structure, use a microcomparator and measure the feature. Multiply the length of the feature as measured by the microcomparator using the map scale to get the feature length. Record all structure lengths in the data table.

Step 2. Determine structure width. Using the road symbol, establish the width of all structures of one or more lanes directly from the map. For tunnels and fords, use only half the width indicated by the symbol, unless other information sources indicate differently. This width reduction is necessary because some structures are built with only one lane to reduce the cost of construction. See Figure 4-2.

Figure 4-2. Transportation legend (tunnels)

Figure 4-3. Depth of overburden for tunnels

Step 3. Determine the depth of overburden. The depth of the tunnel overburden has tactical significance due to the ability to render road or railroad routes impassable to tactical units, especially if bypass capabilities are restrictive. Tunnel overburden is the material, such as soil and rock, that is directly over the tunnel structure. See Figure 4-3. You can obtain true depth determination of the tunnel overburden only by ground measurements or from DA Form 1250, Tunnel Reconnaissance Report. See Figure 4-4. You can estimate depth using aerial photography or mensuration techniques. The least effective method is to use contour lines on a topographic map. If using a topographic map, the maximum depth of the material (for example, soil or rock) laying directly over a tunnel can be estimated.

a. Determine the elevation of the road surface where it intersects with each tunnel portal. Select the portal with the lowest elevation.

b. Locate the highest contour line that passes directly over the tunnel symbol and determine its elevation.

c. Subtract the elevation determined in Step 3a from the elevation determined in Step 3b. This number is an estimated depth of the tunnel overburden. Record it on DA Form 1250 as an estimate.

Step 4. Determine bypass conditions of bridges. You can determine bypass conditions from a detailed study of the total area extending a distance of 2 kilometers on either side of the bridge. Look for the following factors when evaluating bypass conditions: steepness of bank slopes, depth of water, denseness of vegetation, roughness of surface, presence of boulders or approaches, and wet or soft ground.

DA FORM 1250
1 JAN 55

Figure 4-4. Sample tunnel reconnaissance report

Figure 4-5. Transportation legend (bridges)

Identify each bypass as easy (E), difficult (D), or impossible (I) on the line extending from the NATO bridge symbol to the map location. Easy obstacles can be crossed within the immediate vicinity of the bridge by a US 2 1/2-ton 6 x 6 truck (or NATO equivalent) without improving the bypass. Difficult obstacles can be crossed within the immediate vicinity of the bridge, but some work will be necessary to prepare the bypass. Impossible obstacles can only be crossed by repairing the existing bridge or constructing a new bridge. See Figure 4-5.

Fords

A ford is a location in a water barrier where the physical characteristics of the current, bottom, and approaches permit the passage of personnel and/or vehicles.

Estimate the crossing length of a ford from the map symbol by measuring the distance between the stream margins. Streams that show only one line are 25 meters or less in width and cannot be used as fords. See Figure 4-6.

Figure 4-6. Estimating stream margins

Figure 4-7. Transportation legend (Airfields)

$$\text{Estimated Ford Length} = \frac{\text{Map Scale} \times \text{Ford Length}}{1,000}$$

Divide estimated length by 1,000 to change the length to meters.

Ferries

Step 1. Determine travel distance. You cannot determine the actual distance of ferry travel by analyzing the map, because the route indicated on the map is usually an approximation. When ferry terminals are directly opposite each other, you can use the width of the river as an approximate travel distance. If the terminals are located on different maps, determine the straight line open water distance and record it on DA Form 1252, Ferry Reconnaissance Report. When you approximate distances, note this fact adjacent to the length in the reconnaissance report.

Step 2. Sketch the dimensional plan of terminals. US military maps often indicate the plan view of large ferry terminals. Sketch the dimensions of wharves, buildings, and parking lots in plan view on the ferry reconnaissance report indicating all true distances.

Airfields

The four types of data shown for airfields are length, width, pavement status, and orientation.

Step 1. Trace over the runway to show which direction the runway is oriented. At the end of each runway, indicate its azimuth to the nearest 10 degrees by dropping the zero from the numerical value and deriving a one- or two-digit number. For example, if the azimuth is 260 degrees, the number recorded on the runway is 26. Record the azimuth on the overlay.

Step 2. Measure the length and width of the runway using the map scale. If the runways are not wide enough to permit this procedure, you may place the numerals immediately adjacent to the runway. The runway length measurement should exclude the overrun area. Add the information as to whether the runway is paved (P) or unpaved (U), if you know it. See Figure 4-7.

Heliports

Heliports with runways offer evidence that they are designed for heavier wheeled cargo or passenger helicopters, while helipads accommodate rotary wing aircraft

<u>SYMBOL</u>	<u>RAILROADS</u>
	Single track, normal gauge
	Multiple track, normal gauge
	Narrow gauge
	Broad gauge
	Electrified line
	Dismantled line
	Passing track (≥ 280 meters)
	Siding (≥ 280 meters)
	Yard (total track length in meters)
	Bridge length and overhead clearance
	(U = Unlimited overhead clearance)

Figure 4-8. Transportation legend (Railroads)

that do not require a takeoff ground run to become airborne. Label the azimuths of heliports that have distinct runway orientation. Record the dimensions for width and length using the map scale and the procedure shown above in Step 2 of Airfields.

Railroads

Step 1. Determine the correct category from the map legend for railroads and select the proper symbol for each type. Then draw the railroad symbol on the overlay for each railroad in the same category. Follow the railroad throughout its length on the map, looking for points at which either the category or the ID number changes. Position the symbols to conform with mapping standards. See Figure 4-8.

Step 2. Examine the map and legend and determine the track route, gages, and locations of bridges, facilities, and crossings. Note tunnels and spurs as well as suspected crossings.

Step 3. Start tracing the alignment of the railroad across the entire sheet. Continue this process until you have traced all railroad tracks onto the overlay. Where the tracks intersect with a built-up area, continue tracing the railroad through the area. Mark lightly all pertinent features such as bridges, tunnels, and crossings. If the sheets show a track siding, trace it to its end. Measure the length of the siding in meters and record it on the overlay. If the siding has a building or facility indicated or suspected, trace and annotate its location. Certain facilities may sometimes provide electrical tracks for their privately-owned siding or spur. The

track may also become multiple along the siding or spur, if so, you must note this on the overlay.

Step 4. Whenever the route crosses a stream or creek, note the possibility of a culvert on the overlay. You must also identify all road or highway crossings on the overlay, using the proper symbol.

Step 5. Rarely will a railroad grade exceed 3 percent. If the contour interval suggests a greater gradient, note this on the overlay. A slope overlay may be available with the surface configuration overlays, if previously compiled.

Step 6. Locate and trace all railroad cut and fill areas. Much of this data will be deleted from the final overlay. Cuts are potential railroad traffic interdiction sites because of the possibility of slides induced by demolition of steep side slopes.

Step 7. Railroad bridges are normally symbolized on topographic maps. Unfortunately, the type of bridge or construction material is seldom stated. Locate all highway bridges that intersect the railroad route, as well as all railroad-carrying bridges. Draw the bridge symbol on the overlay adjacent to the site. Measure the bridge length in meters and note. This will be relevant bridge data for DA Form 1249, Bridge Reconnaissance Report.

Step 8. Identify the railroad structures. The map legend or map area may have printed data labeling various railroad facilities such as water towers and switching pits.

PHOTO ANALYSIS OF TRANSPORTATION

Oblique Aerial Photography

The scale of oblique photography is difficult to determine, because it constantly varies from the foreground to the background of the photo. If vertical aerial photography is not available and you must use oblique photography to obtain the necessary data, consult the appropriate references.

Aerial Photographic Measurements

Step 1. Determine horizontal measurements. With a magnifier, carefully determine the location of the traveled way of the bridge. Determine the distance between the curbs of the traveled way with the microcomparator, and take the measurement using the metric scale. Multiply the image measurement by the photo scale to determine the true measurement. Record this value on the bridge cross-sectional sketch on DA Form 1249. Determine the length of bridge number 1 by first locating, under stereo viewing conditions, the abutments at each end of the bridge. With the microcomparator, measure the distance between the abutments. Multiply this image distance by the photo scale and record it at the proper place on your sketch. If the bridge is composed of a number of spans, record them on the sketch and in the Bridge Reconnaissance Report.

Step 2. Determine vertical measurements. Obtain vertical measurements, such as the vertical clearance of the bridge and the under-bridge clearance, from stereo aerial photography by using a parallax wedge or bar. Measurements made with these instruments are more accurate than those obtained from a map, but they are

not as accurate as those obtained from on-site measurements or from as-built drawings. Record the distance on the cross-section sketch on the Bridge Reconnaissance Report.

Step 3. Determine under-bridge clearance. Determine the under-bridge clearance (using the same method) by measuring the difference in elevation between the bridge deck and the surface of the feature passing beneath the bridge. Since the bridge substructure will not be visible to you, you will need to estimate the height of the substructure and subtract it from the computed under-bridge clearance distance. Record the under-bridge clearance distance on the sketch on the Bridge Reconnaissance Report.

Step 4. Determine height. Use the parallax bar to determine height. Orient photos and secure them with tape.

Surface Materials and Conditions

Step 1. Estimate surface materials. Figure 4-9 lists the general air photo characteristics of road surface materials. Compare the photo appearance with the table, and estimate the surface material during the map analysis. Consider the route category when the type of material is not readily apparent. For example, national routes are usually concrete or bitumen, while country roads are often gravel.

Step 2. Estimate surface conditions. Surface condition is difficult to estimate except from very large-scale photography. Look for evidence of frequent patching, checks, broken edges, potholes, ruts, and frost or heat heaving.

Step 3. Determine surface materials of medians and shoulders. These materials may be bare ground, grass, trees, shrubs, gravel, bitumen, or concrete. In some instances, the median may be only a wall or barrier and will be difficult to detect. Therefore, use the largest photos and the highest practical magnification available.

Bridges

Step 1. Identify structure features, using oblique photography. Because they provide a side view of the structure, oblique photos are the best some to determine construction type, material, length, overhead and under-bridge clearances, number and type of span, and length of individual spans. Measurement is dependent on careful, accurate determination of the scale. When practical, make duplicate measurements on vertical photography and average the results.

Step 2. Measure bridge features using vertical photography. Measurements on vertical photos are usually more accurate than similar measurements made on oblique photographs, but vertical photos do not provide the side view so useful in determining the type of construction. A definite shadow of the bridge often provides much of the same information available from oblique coverage. When no shadow of the bridge exists, examine the surrounding vertical photographs and look for an image of the bridge that falls near the edge of the photograph. Images near the edge of vertical photos are often displaced or tilted so that the side of the object is visible.

Step 3. Determine the military load class. You cannot determine the military load class directly from aerial photography, but you can roughly estimate it from vehicles that were using the bridge at the time the photo was taken. Examine the

AIR PHOTO CHARACTERISTICS OF ROAD SURFACE MATERIALS					
FILM TYPE	CONCRETE	PAVING STONE	BITUMEN	GRAVEL	SOIL
Panchromatic	- Center line present - Definite margins - Light tone	- Center line present - Light to dark tone depending on materials - Pattern of blocks may be detectable	- Center line present - Indefinite margins - Dark tone	- No center line - Indefinite margins - Light to dark gray tone	- No center line - Indefinite margins - Tone dependent on soil color
Black and white infrared	- Center line present - Definite margins - Light tone	- Center line present - Light to dark tone depending on material - Pattern of blocks may be detectable	- Center line present - Indefinite margins - Dark tone	- No center line - Indefinite margins - Light to dark gray tone	- No center line - Indefinite margins - Tone dependent on soil color
Color	- Center line present - Definite margins - Light tone	- Center line present - Light to dark tone depending on material - Pattern of blocks may be detectable	- Center line present - Indefinite margins - Dark tone	- No center line - Indefinite margins - Light to dark gray tone	- No center line - Indefinite margins
Color infrared	- Center line present - Definite margins - Light tone	- Center line present - Light to dark tone depending on material - Pattern of blocks may be detectable	- Center line present - Indefinite margins - Dark tone	- No center line - Indefinite margins - Light to dark gray tone	- No center line - Indefinite margins

Figure 4-9. Air photo characteristics of road surface material

photos and identify any vehicles on the bridge. If you can estimate the load class of the vehicle, you can assume that the class of the bridge is at least the same. If no vehicles are actually on or approaching the bridge, the load class cannot be estimated.

Step 4. Identify construction type and materials. On large-scale aerial photography (1:2000 to 1:15,000) such as panchromatic and color, you can easily identify construction type and materials such as masonry, wood, steel-reinforced concrete, and steel by indicators on the photos. These indicators include shadow and photographic tone, color, and texture. With detailed study of the photographs, especially under stereo conditions, you should be able to determine not only the type of construction but also the major structure composition.

Step 5. Determine bypass conditions. The standard topographic map will supply all the necessary information to determine bypass conditions for each bridge and LOC structure. However, you must use aerial photography to continuously update the map, particularly under combat conditions. To determine bypass conditions from aerial photography, study the area adjacent to the structure under stereo conditions and note any indications of shallow water, such as sandbars or rocks, that are visible through the water surface. In addition, look for vehicle tracks along the river bank that indicate the location of an existing ford. When the structure is a dam used as a bridge, examine the downstream side of the dam, where the water is often shallow enough to be used as a bypass. Because dams are almost always situated where bedrock is close to the surface, stream bottom conditions are usually firm enough to support most vehicle types.

Ford Width

Look for indications that the roadway continues across the channel, such as two faint lines that mark the sides of the traveled way. On some fords, the sides of the roadway are marked by boulders that appear on the imagery. Where the ford has been raised by adding material to the bottom of the stream, the sides may appear as lines of ripples or as eddies of a lighter tone than the surrounding water. Measure the width.

Ford Bottom Characteristics

Determining ford bottom characteristics such as paved, rocky, and sandy from aerial photography depends on a number of factors. They include water depth and clarity, film type, and photo scale. To determine this data, orient aerial photos of the ford for stereo viewing using proper procedures. Study the area around the ford, as well as the river or stream channel both upstream and downstream of the ford.

Rapids, white water, and exposed rocks or boulders indicate a rocky bottom. Bars, braiding, and steep banks often indicate coarse-grained material such as sand or gravel. Meanders and oxbows in the immediate vicinity indicate relatively slow-moving streams with fine-grained material. Angular drainage patterns with frequent sharp changes in direction indicate rock control and a rocky bottom. In swift-flowing streams in mountainous areas, fine materials do not settle; therefore, the bottoms are usually rocky or firm.

Length of Ferry Crossing

You can easily determine ferry crossing length from aerial photography if both terminals appear on a single photograph. If two or more photos are required, construct a mosaic of several photos.

Single Photo Method

Determine the scale of the photo, using proper procedures. Locate terminals and measure the open-water distance between terminals with the microcomparator or PI scale. Multiply the measured distance by the denominator of the representative fraction to determine true distance.

Mosaic Method

Determine the number of photos required to cover the entire open-water distance between ferry terminals. Secure the photo containing the most western terminal to a suitable flat surface. Carefully place the adjacent photo over the edge of the first photo, aligning common terrain features of Photo 2 with Photo 1. Continue this process until the second ferry terminal appears on a photo. Check your work, making certain that all photos are properly aligned.

Scale the open-water distance between ferry terminals. Multiply the photo distance by the denominator of the photo representative fraction.

Ferry Terminal Layout

Step 1. Orient the photos for each terminal, using proper procedures, and examine the terminal facilities and approaches.

Step 2. Examine the land facilities. Look for large buildings, parking lots, winches, guy-line towers, and any other features that may affect the use or capacity of the site. When feasible, determine the dimensions of the site and major structures.

Step 3. Examine the water approaches. Look for obstacles, fenders, piers, pilings, and evidence of the channel.

Step 4. Analyze vessel information such as ferry length, beam, and capacity. To do so, you will need to orient photos, locate one or more of the vessels, and determine the photo scale. With the microcomparator, measure the length and width of each vessel. Multiply the photo distances by the denominator of the photo scale to determine true distances.

Step 5. Estimate the number of vessel decks capable of carrying vehicles. Assume an automobile size of 2 by 6 meters and a weight of 2 tons.

Step 6. Estimate vehicle capacity for one deck of the vessel. Multiply this number by the number of decks. If all vessels do not have the same length and beam, measure and record each vessel separately.

Step 7. Examine approach conditions for fords and ferries. Approaches are classified as easy when the slope is 7 percent or less; the surface is relatively smooth with no ruts, potholes, or other obstacles; the width is at least 3 meters; there are no sharp curves within 50 meters of the water's edge and the surface is well drained

or free of standing water. Failure to meet all of these conditions will result in the approach being classified as difficult.

Airfields

Step 1. Using the PI and photographic scales, measure the length and width of the runway. Record the measurements in meters on the factor overlay within the runway boundary lines or beside the runway.

Step 2. Determine the surface material of the runway using the information in Table 4-2. Label runways with hard or paved surfaces with a *P*, and loose or unpaved surfaces with a *U*.

AIRFIELD SURFACE MATERIALS INFORMATION			
Type of surface	Surface outlook	Color	Other
Sod	Irregular	Brown to green mottled (color photos)	Tire tracks
Graded earth, gravel, sand, coral, clay (sources of surfacing material)	May have grader marks	Light to dark color, mottled	Open pits in the vicinity
Pierced metal	Grid pattern	Brown to green, mottled	Piles of plank in area
Concrete	Smooth, surface may be patched or painted	Light gray to white, uniform	Block pattern
Asphalt	Smooth, surface may be patched or painted	Very dark to light gray, usually uniform	None

Table 4-2. Airfield surface materials information

Step 3. At most major airfields, the magnetic alignment of runways is painted in large numerals at the ends of the paved surfaces. These azimuths, contrasting with the runway coloration, may be legible on aerial photography. Transfer these values to the ends of runways shown on the factor overlay. If the numerical designations of runway azimuths do not appear or are illegible on the photography, measure the magnetic orientation of each runway and enter the values at the ends of the runways.

Railroads

Step 1. From the stereo pairs, locate the area of the railroad to analyze. Compare the date of the photographs with the date of the last map revision or update. If the photographs are more recent than the map, use them. If the map is more recent, give greater weight to the map information however, even if it is more recent, it should not always take precedence over the photographs, because map information is often general. As a result, some feature such as sidings are not shown.

Step 2. Look for any railroad sidings not shown on the map. Compare the outline of all built-up areas on the photos with the map symbols of the same areas. Lightly sketch any new alignments or built-up areas onto the overlay in pencil.

Step 3. Verify the location of each segment end point. If the end points determined from the photo differ from those obtained from the map, use the points obtained from the photos. Relocate the endpoint symbols on the overlay, renumber the segments if necessary, and determine the coordinates of the relocated points. Change entries in the railroad data tables if necessary.

Step 4. Verify the gradient of each segment that has a grade of 3 percent or greater.

Step 5. Examine aerial photography to verify the location of culverts or streams. The map indicates the location of culverts or streams passing beneath the railroad. Also check all areas on the photos where a stream or drainageway intersects a railway. If these areas indicate culverts, annotate the overlay at each location. Make notes in the data tables as necessary.

Step 6. Locate built-up areas on aerial photos that show railway through-routes. Locate any zones where buildings, walls, and so forth constrict the width of the route to less than 4 meters. Measure the constrictions, using the microcomparator or the PI scale, and record the data in the proper place on the overlay.

Step 7. Examine and verify areas previously identified as level crossings. Make additions, deletions, or changes on the overlay as required.

Step 8. Determine catenary clearance. The clearance beneath the catenary is required only if the railroad under study is electrified and uses overhead wires. The catenary clearance is seldom shown on maps. Photos may provide some indication of catenary clearance. If not, place a question mark above the crossings on the overlay to indicate there are overhead wires but the clearance is unknown.

Step 9. Assemble the vertical photos that provide stereo coverage for each bridge recorded on the factor overlay. If oblique photos are available, place them with the vertical ones. Study the material carefully to become familiar with the general characteristics of the bridge. Determine the number of spans, overhead clearance, and so forth. Measure the roadbed widths. Record all data in Railroad Data Table 2 or annotate it on the overlay.

Inland Waterways

Classify inland waterways according to their depths. Very shallow waterways have depths less than 1.4 meters. Medium waterways have depths between 1.4 and 2 meters. Deep waterways have depths greater than 2 meters. See Chapter 2 for more information.

Facilities and Installations

Step 1. Identify all wharves. Figure 4-10 shows a reference diagram of a wharf.

Step 2. Identify all locks. Common types of locks are single and multiple-chamber. See Figure 4-11. Gates are the most vulnerable features of a lock. Common types of gates are--

- Double-leaf miter gates (see Figure 4-12). A pair of hinged gates that form a V or angle across the end of the lock when closed. The apex is always upstream to use the head of water to keep the gates closed.
- Single-leaf miter gates. Hinged gates that pivot into a recess in the lock wall. See Figure 4-13.
- Vertical-lift gates. Lock gates that move in a vertical plane. Those gates are usually suspended from an overhead frame and counterbalanced.

Figure 4-10. Wharf reference diagram

- Caisson or sliding (retractile) gates. Those gates move horizontally into wells or caissons when open.
- Segmental gates. A pair of gates shaped like sectors of a cylinder. They are hinged at the sides and rotate into wells.

Step 3. Prepare final overlay. See Chapter 8 for procedures.

URBAN AREAS

Step 1. Obtain a 1:50,000-scale map covering the area of interest. Register the mylar to the map or data base and annotate the marginal information. Then locate and outline all areas that cover the area to be studied.

Step 2. Establish a numerical priority listing (ranking) of urban areas to be analyzed at a scale of 1:12,500. Determine this sequence based on whether the areas are administrative centers (state and national capitals, strategic centers of

Figure 4-11. Types of locks

Figure 4-12. Miter gate locks

production, steel, manufacturing, and nuclear power plants), or are located on dominant ground or on major avenues of approach.

Step 3. Assign a priority number to each urban area and carry out the analysis accordingly. Where all urban areas on a 1:50,000-scale map are to be analyzed without concern for priority consideration, number each area, beginning at the top left corner of the identification overlay, and proceed across and down the map.

Step 4. Retrieve a 1:12,500-scale topographic map of the urban area. If you cannot find any, outline the desired area on the 1:50,000-scale map and enlarge this map segment by 400 percent. If a 1:25,000-scale map is available, you may enlarge

it by 200 percent. The enlarged map will become the base map to which all factor overlays will be registered.

You will require multiple overlays to extract information for the data fields documented in order to map adequately the diverse terrain features that make up the urban area. In this regard, the number of overlays to be used is considerably greater than the number used in other areas. Some topics include vegetation, roads and related structures, drainage and water resources, and railroads and related structures. Because of the larger scale of the urban-area products and the complexities inherent in this unique terrain, some elements are portrayed differently from those depicted on overlays keyed to 1:50,000-scale maps.

Step 5. Determine the area to be analyzed and gather all necessary aerial photographs in stereo pairs to cover the area. Orient them for stereo viewing.

Step 6. View the photographs in stereo and use the PI keys and text to determine the urban type in the aerial coverage. Then analyze, outline, and identify all types and label them with the appropriate urban code.

Step 7. Determine the roof coverage. Density refers to the ratio of roof area of buildings to total ground area, including streets and small open spaces. To determine roof cover percentage from aerial photography, collect the necessary stereo pairs for the area to be analyzed and note the photo scale. Measure the footage of the area, both the length and width, with a thousands-foot scale and multiply it by the photo scale.

$$GD = PD \times PSR$$

$$\text{Area} = L \times W$$

Where--

GD = ground distance

PD = photo distance

PSR = photo scale reciprocal

L = length

W = width

Step 8. Determine the roof size by measuring the average roof in the area the roofs should all be about the same size. Using the microcomparator, measure the length and width of an average roof and multiply it by the photo scale. Then count the number of buildings and multiply that number by the area of the roofs. To determine the percentage of the roof coverage, take the roof size times the number of buildings in the area, divide it by the total area, and multiply it by 100.

$$\frac{\text{Total area of buildings} \times \text{Number of buildings in area} \times 100}{\text{Total area size}} = \% \text{ Roof coverage}$$

Figure 4-13 will help determine the percentage of roof coverage and the percentage of concealment from aerial detection. Use the appropriate symbol to mark the overlay.

Symbol	% Roof coverage	Category	Concealment
5 	75-100	Congested	Excellent
4 	50-75	Dense	Good
3 	25-50	Moderate	Fair
2 	5-25	Sparse	Poor
1 	0-5	Open	None

Figure 4-13. Concealment from aerial detection and percentage of roof coverage

Step 9. Determine construction and building type. Make appropriate annotations for type of construction or building, using the definitions below. Note: Building types 5 through 8 are comprised of multistory office and apartment buildings. For the purpose of classification and subsequent evaluation, each category is divided into low-rise buildings of six stories or less and high-rise structures in excess of six stories.

- **Type 1.** Wood and timber frame construction. Most farm buildings and those buildings constructed prior to the late 19th century are classified as Type 1. Their ceilings with wooden rafters and weak exterior walls offer little protection from indirect or direct weapons fire. Internal communications routes are excellent since their lightly constructed walls are easy to breach; however, significant reinforcement is required to provide protective cover if such buildings are to be used as defensive positions. Within larger built-up areas, Type 1 buildings present the greatest fire hazard. See Figure 4-14.
- **Type 2.** Masonry construction. Buildings with strong walls of brick or natural stone constructed in the 19th and early 20th centuries are classified as Type 2. These buildings, typified by the old town hall, are commonly found in the central areas of towns and cities. They generally contain from two to four stories with ceilings with wooden rafters and lightly constructed tile roofs. Presenting less of a fire hazard than wood and timber frame structures, Type 2 buildings are frequently suitable as defensive positions. While internal communication routes are excellent, external walls are difficult to breach without heavy weapons or demolitions. See Figure 4-14.

Figure 4-14. Examples of construction/building type (wood and frame and masonry)

Type 3. One- or two-family dwellings. Family dwellings constructed of solid or insulating bricks or of cinder blocks with ceilings of reinforced concrete are classified as Type 3. Such buildings frequently contain strongly constructed basements. Type 3 buildings offer significant protection and require little reinforcement if used as defensive positions. Because of Type 3 construction, fire hazards are minimal. If demolished, significant rubble is generated, offering protection to the defender or creating an obstacle to the attacker. See Figure 4-15.

Figure 4-15. Example of construction/building type (family dwellings)

- *Type 4.* Prefabricated one-family dwellings. Prefabricated family dwellings assembled with precast and light building materials are classified as Type 4. In most cases, the cellars or basements are strongly constructed. Unlike Type 3 dwellings, these buildings require significant reinforcement if they are to be used as defensive positions. They also constitute a fire hazard in a freed defense. Rubble produced by their destruction creates an effective obstacle and additional cover for ground-level defensive positions. See Figure 4-15.
- *Type 5.* Low-rise office buildings. Multistory office buildings, with their steel frame and reinforced concrete construction, are normally characterized by large expanses of plate glass which offer little protection. See Figure 4-16.
- *Type 6.* High-rise office buildings. These buildings are also characterized by large expanses of plate glass which offer little protection, but they have six stories or more.
- *Type 7.* Low-rise apartment buildings. While similar in size to low-rise office buildings, they generally have smaller glass areas and load-bearing reinforced concrete exterior walls which provide greater protection.
- *Type 8.* High-rise apartment buildings. See Type 4, paragraph 2. See Figure 4-16.
- *Type 9.* Buildings common to newer industrial and warehouse complexes are classified as Type 9. While the type construction may vary considerably, steel framing and the use of lightweight materials for exterior walls and roofs are normal practices. Reinforced concrete floors and ceilings are frequently used in multistory buildings.

Figures 4-17 through 4-31 show examples of industrial areas that will be useful in identifying specific subdivisions of the industrial classification.

This completes the urban analysis procedure. See Chapter 8 for final overlay preparation procedures.

LINE OF COMMUNICATION, COVER AND CONCEALMENT

Chapter 5

LINE OF COMMUNICATION

Lines of communication (LOC) are all the routes (land, water, and air) that connect an operating military force with a base of operations and along which supplies and reinforcements move. An LOC map is especially important to transportation corps and logistics personnel. It is also important for planning the interruption of enemy supplies. This map differs from the CCM map in that it shows routes over which supplies rather than deployed forces will move, so it depends more heavily on existing roads, railroads, and airfields.

Roads

Step 1. Study the requirements from corps and division before preparing specifications for synthesizing LOC roads.

Step 2. Examine the base map and become familiar with the LOC study area road net.

Step 3. Examine the transportation factor overlay, to select the major and secondary roads, the on-route fords, ferries, tunnels, galleries, and snowsheds for the LOC study. Identify major road categories to be used in the LOC study, such as all-weather hard surface and fair-weather loose surface.

Step 4. Examine the data tables to select the essential data elements listed on Table 1. See Figure 5-1.

Step 5. Obtain aerial photos for the area of interest to verify and update information.

ROADS	BRIDGES AND OVER-PASSES	**FORDS	**FERRIES	*TUNNELS, GALLERIES AND SNOW-SHEDS	AIRFIELDS	RAILROADS
Identification Number	*Length	Length	Crossing length	*Length and width	Identification	*Electrified
Category (highway, routes, autobahns, etc.)	*Width	Width	Vessel characteristics	Construction Details	*Runway orientation	*Abandoned
Segments	Load class construction type	Depth	Approaches	Overburden	Type	Routes
*Type	*Clearances	Bottom conditions	Load class	Clearances	*Surface material	*Yards/ terminals
*Width	*Bypass potential	Approaches			Parking facilities	Rolling stock
Surface materials and conditions					Hangars	Junctions/ crossings
Shoulders					POL	*Track(s)
Medians					Ammo/bomb storage	*Gage(s)
Obstacles					Quarters	Bridges
Culverts					*Elevation	
Cuts and fills					*Length/ width	
Turn-outs, emergency drive-offs and parking areas						
Level crossings						
Constrictions						
Grades						
Sharp curves						
Road or bridge under construction						
* Data elements deemed essential for LOC synthesis						
** Names and locations only						

Figure 5-1. Major data elements for LOC products

Step 6. Prepare an informal layout from alternate photos. Examine the road network, correlating the roads selected for the LOC study with the photos. Also examine the tunnels, galleries, snowsheds, ferries, and on-route fords.

Step 7. Stereoscopically examine the selected roads, tunnels, galleries, snowsheds, ferries and on-route fords to ensure that there are no changes or errors in the data-base parameter information. Revise and record any changes.

Step 8. Recheck all gathered information on roads, tunnels, galleries, snowsheds, ferries, and on-route fords to ensure that the selected roads meet with the user's request.

Step 9. Compile all pertinent data and draft it onto a clean overlay. Make sure the data pertains to the LOC, since not all data on factor overlays is necessary for an LOC overlay. See Figure 5-2.

See Figure 5-2 for typical roads and related structures found on a factor overlay. The data is derived from an analysis of maps, literature, and photos, and the details for the data elements are recorded on a roads factor overlay data table, which shows more than you need for a study. After examining the map area and identifying the LOC relevant data elements, check the available aerial photography of the area.

Bridges and Overpasses

Step 1. Study the requirements from corps and division before preparing specifications for synthesizing the LOC.

Figure 5-2. Sample annotated LOC overlay

Step 2. Examine the base topographic map to become familiar with the LOC study area.

Step 3. Examine the bridge section of the transportation factor overlay to select pertinent information.

Step 4. Examine the bridge data table to select the data elements listed on Table 1 for each relevant LOC.

Step 5. Obtain aerial photos for the area of interest to verify and update information.

Step 6. Prepare an informal layout from alternate photos. Examine the road network and locate the bridges selected for the LOC study area.

Step 7. Stereoscopically examine the selected bridges for any changes or errors in data-base parameter information. Revise and record any changes.

Step 8. Recheck all gathered bridge information to ensure the selected bridges meet with the user's request. You must show all bridges greater than or equal to 18 meters.

Step 9. Record only the pertinent information on the draft LOC. See Figure 5-2.

Railroads

Step 1. Study requirements from corps and division before preparing specifications for synthesizing the LOC railroads.

Step 2. Examine the base topographic map to become familiar with LOC study area railroads.

Step 3. Examine the transportation factor overlay to select LOC areas of interest.

Step 4. Examine the railroad data table to select the essential data element information as listed in Figure 5-3.

Step 5. Obtain aerial photos for the area of interest to verify and update information.

Step 6. Prepare an informal layout from alternate photos. Examine the area railroads and locate the segments selected for the LOC study area.

Step 7. Stereoscopically examine the selected railroads for any changes or errors in data-base parameter information and make necessary revisions.

Step 8. Recheck all gathered information to ensure that selected railroads meet with the user's request.

Step 9. Outline all information on the draft overlay.

PARAMETER	FACTOR	CRITERIA
Good	Slope	>30%
	Canopy closure	> 50%*
	C3 C4 D3	D4 E3 E4
	Roof Covered**	>40%
Fair	Slope	10-30%
	Canopy closure	<50%
	C1 C2 D1	D2 E1 E2
	Roof Coverage**	20-40
Poor	Slope	<10%
	Non-forested	A1 B G
	Roof coverage**	<20%
* Or stem spacing 5m		
** If evaluated		

Figure 5-3. Cover from flat trajectory weapons

Note : Criteria may not be applicable to your unit.

Airfields

Step 1. Study requirements from corps and division before preparing specifications for synthesizing the LOC airfields.

Step 2. Examine the base topographic map to become familiar with the LOC study area.

Step 3. Examine the transportation factor overlay to select pertinent areas of interest.

Step 4. Examine the airfield data table to select the essential data elements information as listed in Figure 5-3.

Step 5. Obtain aerial photos for the area of interest to verify and update information.

Step 6. Prepare an informal layout from alternate photos. Examine the airfields and locate the segments selected for the LOC study area.

Step 7. Stereoscopically examine the selected airfields for any changes or errors in data-base parameters information, and make necessary revisions.

Step 8. Recheck all gathered information on airfields to ensure that selected airfields meet the user's request.

Step 9. Outline all information on the draft LOC overlay.

Remaining Factor Overlays

Step 1. Check the soils factor overlay to what effect soil conditions will have on unsurfaced routes. Consider the probable weather to see if it might cause

surfaces to be muddy, frozen, dry, or dusty and to see if the expected condition will be favorable or unfavorable to movement along the roads.

Step 2. Check the vegetation factor overlay and mark any areas where vegetation will conceal the mute. Show the percent of canopy closure at the given time of year.

Step 3. Check the drainage factor overlay to locate and mark areas where flooding might impede movement, to see if any rivers must be bridged or forded, and to see what trussing facilities exist. Figure 5-4 shows steps to be followed in the synthesis process from existing factor overlays and data tables.

COVER FROM FLAT TRAJECTORY WEAPON

Cover, or protection from enemy fire, is a vital part of military operations. Examples are rocks, river banks, vegetation, quarries, walls, and buildings.

Step 1. Study requirements from the requester.

Step 2. Obtain source materials, including the base topographic map, photography, and vegetation and slope-factor overlays.

Figure 5-4. LOC synthesis process

PARAMETER	ROOF COVERAGE	VEGETATION CATEGORY		PERCENT CHANCE OF DETECTION
	Percent	Summer	Winter	
Best	>40%	C4, D4, E4, F4, I4	C4	0-25
Good	20-40	C3, D3, E3, F3, I3	C3	25-50
Fair	<20	B2, C2, E2, F2, I2, M	B2, C2, E3, E4	50-75
Poor		A1, B1, C1, D1, E1, F1, G1, G2, H, I1, J, K, L, N	A1, B1, C1, E1, E2, *D, *F, *G, H, J, K, L, N1, N2	75-100
* Or stem spacing 5m				

Figure 5-5. Concealment from aerial detection summer or wet season

Step 3. Review source materials.

Step 4. Determine what parameters each category falls into (good, fair, or poor). To construct a cover overlay, you must consider slope, vegetation, and, roof coverage (if it is evaluated).

Note: This particular criteria being used may not be applicable to your unit. It should be revised to meet your units specific needs.

Step 5. Draft the cover overlay.

CONCEALMENT FROM AERIAL DETECTION

Concealment is protection from observation. This overlay is important for judging where the enemy might be located. It is especially important in areas where guerrilla forces might be operating, because it helps the commander predict attacks. Concealment may be provided by woods, underbrush, snowdrifts, tall grass, cultivated vegetation, roof coverage, or any other feature that denies observation.

Step 1. Study the requirements and determine if concealment is for the summer (wet) season or for the winter (dry) season.

Step 2. Obtain the base map, aerial photography, and the proper seasonal vegetation factor overlay.

Step 3. Review the vegetation factor overlay with the base map and aerial photography to ensure that all vegetation categories are shown correctly. A deciduous forest with 25 to 50 percent canopy closure is a D2 vegetation code on the data-base factor overlay and is a fair area for concealment. A mixed forest with 0 to 25 percent canopy closure is an E1 vegetation code on the data-base factor overlay and is a poor area for concealment. The type of vegetation and the canopy closure are the two main factors you should check on the vegetation factor overlay.

Step 4. If evaluated, roof coverage is also used as protection from observation. You will probably look at this more in winter than summer because of the lack of vegetation during winter. Use Figure 5-5 to determine which parameter each vegetation category and roof coverage will fall into.

Step 5. Draft a concealment overlay.

CROSS-COUNTRY MOVEMENT

Chapter 6

PREPARE CCM OVERLAY

The cross-country movement (CCM) overlay is sometimes referred to as an avenue-of-approach map because it tells the best routes by which various vehicles can get to an objective when they cannot use prepared roads. It also shows parts of terrain that these vehicles cannot cross.

Step 1. Assemble source materials. These will include the base topographic map, aerial photography, slope (surface configuration), vegetation and soils (surface materials) factor overlays, and the following tables:

- Table 6-1, Vehicle characteristics.
- Table 6-2, Slope/speed characteristics.
- Table 6-3, Soils factor (dry and wet).

VEHICLE	M1	M60A1	M109	M113	M35A2	M151	T62	T72	M2	M3	M48 AVLB	M60 AVLB	MLRS

Table 6-6. Vegetation factor data

Step 2. Determine the vehicle to be used and whether the CCM product will be prepared for dry or wet conditions or both.

Step 3. Procure the surface configuration factor overlay and Tables 6-1 and 6-2.

Step 4. Compute the F1 speed / slope factor. This calculation determines the extent that any slope will deteriorate the speed of the vehicle without consideration for any other physical factor.

Using Table 6-1, determine the maximum off-road gradability (kph), maximum on-road gradability (%), and maximum road speed (kph). Record this information in the appropriate column of Table 6-2.

Table 6-7. Speed prediction tabulation sheet

From the surface-configuration overlay, determine the percent of ground slope for slope categories A through F. Use the mid-point value of the slope category as ground slope, as shown below.

$$\text{Formula: mid-point} = \frac{\text{highest value} + \text{lowest value}}{2}$$

Example: Slope category = 10 to 20%

$$\text{Ground slope} = \frac{20 + 10}{2}$$

$$\text{Ground slope} = \frac{30}{2}$$

$$\text{Ground slope} = 15\%$$

Record values of ground slope in the appropriate columns of Table 6-2.

Calculate F₁ values for each slope category.

$$\text{Formula: } F_1 = \frac{\text{maximum off-road gradability (\%)} - \text{ground slope (\%)}}{\text{maximum on-road gradability (\%)} \text{ maximum road speed kph}}$$

a. Negative values indicate No-Go areas, use F₁ = 0.

b. Round values to nearest hundredth, then post them on Table 6-2.

Note: Rounding is critical to the final value.

c. F₁ for map unit G (naturally or culturally dissected terrain) represents an unusual case and is best represented by using the lowest F₁ value obtained that still permits movement.

Example: Calculate the slope category for the M113 (see Table 6-1).

$$\begin{aligned} \text{Maximum off-road gradability} &= 45\% \\ \text{Maximum on-road gradability} &= 60\% \\ \text{Maximum road speed} &= 48 \text{ kph} \\ \text{Ground slope} &= 15\% \text{ (midpoint of 10-20\%)} \end{aligned}$$

$$F_1 = \frac{45 - 15}{60 - 48}$$

$$F_1 = \frac{45 - 15}{1.25}$$

$$F_1 = \frac{30}{1.25}$$

$$F_1 = 24.0 \text{ kph}$$

d. Record F₁ values on Table 6-2.

Step 5. Calculate F2, slope-intercept-frequency (SIF) factor. SIF is the number of times the ground surface changes between positive and negative slopes over a one-kilometer distance. Measuring this is extremely time-consuming in the field, so use the expedient method.

a. Register the surface-configuration overlay to the appropriate topographic map. In a slope category on the overlay, lay a line equal to the length of a diagonal of a one-kilometer square (approximately 1.4 times the length of 1 kilometer on the map).

b. Count the number of times any contour line within the slope category crosses or touches the diagonal.

c. Lay out a second line at right angles and count intercepts as before.

Note: A prepared template will greatly speed this operation.

d. Repeat this procedure at least ten times for each slope map unit, then average the counts. See Figure 6-1.

Figure 6-1. Surface configuration (slope)

e. Repeat this procedure for all slope categories A through F.

f. Adjust the average counts to the standard 1:50,000-scale map with a 20-meter contour interval.

1) Determine the adjusted count, using the formula--

$$\text{adjusted count} = \frac{\text{average count} \times \text{contour interval map used}}{\text{standard contour interval}}$$

Example:

Contour interval of map used = 10 m

$$\begin{aligned}
 \text{Average SIP count} &= 24.4 \\
 \text{Standard contour interval} &= 20 \text{ m} \\
 \text{Adjusted count} &= \frac{24.4 \times 10}{20} \\
 &= \frac{24.4}{2} \\
 &= 12.2 \text{ (Round to 12 or the nearest whole number).}
 \end{aligned}$$

2) Compute F₂ values for each slope category, using the formula--

$$F_2 = \frac{280 - \text{SIF count (adjusted)}}{280}$$

Example: SIP = 12

$$F_2 = \frac{280 - 12}{280}$$

$$F_2 = \frac{268}{280}$$

$$F_2 = .96$$

3) Round values to the nearest hundredth, and record them on Table 6-2.

4) Record the lowest F₂ value on map unit G.

Step 6. Calculate F, slope/SIF - speed calculation. This calculation gives the calculated speed based on the effects and variation of slope.

a. Compute F values using the formula

$$F = F_1 \times F_2.$$

Example: F_{1/2} = F₁ x F₂

$$F_{1/2} = 24.0 \text{ kph} \times .96$$

$$F_{1/2} = 23.04 \text{ kph}$$

b. Record F in the appropriate column of Table 6-2.

Note: The value F will tell you what effect slope will have on vehicle speed.

Step 7. Obtain F₃ vegetation factor.

a. Procure the vegetation-factor overlay and vegetation-roughness tables, Tables 1 and 6. Continuing with the previously selected vehicle, compute the F₃ vegetation factor.

b. Using Table 6-1, determine the vehicle width in meters (m), maximum override diameter (m), and minimum turning radius (m) and record them on Table 6-6.

Figure 6-2. Vegetation

c. From the vegetation factor overlay, determine the forest types and list them in alphanumerical sequence on Table 6-6. List all other vegetation after the forest types. See Figure 6-2.

d. From the vegetation roughness table on the vegetation-factor overlay, determine the stem diameter (m), stem spacings (m), and vegetation-roughness factor for the appropriate forest types and record the information on Figure 6-6. See Figure 6-3.

CODE	FOREST TYPE AND CANOPY CLOSURE															
	C1	C2	C3	C4	D1	D2	D3	D4	E1	E2	E3	E4	F1	F2	F3	F4

								41 5.0 1								

Figure 6-3. Stem diameter(cm)-tree spacing(m)-vegetation roughness

Figure 6-4. Soils

e. For nonforest types, place the vegetation roughness factor in the appropriate location on Table 6-2. For all forested areas, calculate V_1 and record it on Table 6-6. V_1 is the product of the vehicle factor (V_F) and the vehicle clearance factor (V_{1a}). V_F accounts for the response of drivers when approaching wooded areas. V_{1a} accounts for the physical ability of a vehicle to maneuver between tree stems in a wooded area.

Formula:

$$V_1 = (V_F)(V_{1a})$$

Where--

$$V_F = \frac{SS - SD - W}{W}$$

$$V_{1a} = \frac{SS - SD - W}{MTR - 4W}$$

SS = Stem Spacing (m)

SD = Stem Diameter (m)

W = Vehicle Width (m)

MTR = Minimum turning radius (m)

Notes:

1. if V_F or $V_{1a} \leq 0$, $V_{1a} = 0$
2. if $V_F \leq 1$, $V_F = 1$
3. if $V_{1a} \leq 1$, $V_{1a} = 1$.

f. Calculate V_2 for all forested areas and record it on Table 6-6. V_2 is the calculation used to determine if it would be easier for the vehicle to override the trees rather than maneuver between them. The VT portion of the formula is used to calculate the minimum number of trees a vehicle can hit at one time.

Formula:

$$V_2 = 1 - \left(VT \left(\frac{SD^2}{OD^2} \right) \right)$$

$$VT = \frac{W + SD}{SS}$$

Notes:

1. if $SD > OD$, $V_2 = 0$.
 2. if $V_2 \leq 0$, $V_2 = 0$.
 3. if $VT \leq 1$, $VT = 1$.
- g. Calculate F_3 = Select the larger value between V_1 and V_2 .

Formula: $F_3 = (VR)(V_1 \text{ or } V_2)$

VR = vegetation roughness factor (obtain from the vegetation overlay)

Notes:

1. If $F_3 > 1.0$, $F_3 = 1.0$
2. If $F_3 > 0$, $F_3 = 0$ (No-Go)

h. Record F_3 values on Table 6-5.

Step 8. Procure the soil factor overlay and Tables 1, 3, and 4. Continuing with the previously selected vehicle, compute the F_4 soil factor. This calculation will determine if a particular soil type will support vehicular movement and to what extent the speed will decrease due to that soil type. See Figure 6-4.

a. Using Table 6-1, determine the vehicle cone index (VCI_1) for one pass and the vehicle cone index (VCI_{50}) for fifty passes. Record them on Table 6-3.

b. From the surface-materials factor overlay, extract the appropriate soils map units, such as ML1, SM2, and OH0, and post them on Table 6-3.

Note: The third digit refers to the surface-roughness code.

c. From Tables 6-1 and 6-4, determine appropriate RCI values for dry and/or wet conditions and post them on Table 6-3.

d. Calculate the dry-soil factor (F_{4D}) and/or wet-soil factor (F_{4W}) for each soil type.

Formula: $F_{4D} = \frac{RCI_D - VCI_1}{CI_{50} - VCI_1}$

$$F_{4W} = \frac{RCI_W - VCI_1}{VCI_{50} - VCI_1}$$

Notes:

1. if $F_4 \leq 0$, $F_4 = 0$ (No Go)
2. if $F_4 \geq 1$, $F_4 = 1$

e. Record F_4 values on Table 6-4.

CONSTRUCT COMPLEX FACTOR OVERLAY

Step 1. Register the overlay to the base map.

Step 2. Outline the built-up areas (color in red).

Step 3. Outline the open-water areas (color in blue).

Step 4. Using the surface-configuration overlay and the vegetation-factor data table, register complex overlay to the factor overlay and outline the slope areas (color No-Go areas in yellow).

Step 5. Using the vegetation factor overlays and Table 6-3, vegetation factor data, register the complex overlay and outline the vegetation areas (do not draw lines through areas already colored). Color No-Go areas in yellow, and disregard areas less than 250 x 250 meters at map scale (5mm for 1:50,000) or narrow areas less than 100 meters in width at map scale (2mm for 1,50:000).

Step 6. Using surface-materials factor overlay and Table 6-4, soil factor (dry and wet data), follow the procedures in Step 5.

Step 7. Beginning in the upper left corner, number the noncolored areas from 1 through 99. If you have more than 99 areas, outline the first area of 99 and label it as Sector A. Number remaining areas 1 through 99, as before, and label them as Section B. Continue numbering areas and sectors as required.

Step 8. Annotate all sector and area numbers on Table 6-5.

Step 9. Compute CCM speed.

a. Using the completed complex factor overlay and the surface-configuration factor overlay, determine the appropriate map unit for each area and post it on Table 6-5.

b. Determine the $F_{1/2}$ value for the map units from Table 6-2 and post it on Table 6-5.

c. Using the complex factor overlay, the vegetation overlay, and Table 6-3, determine the map units and F_3 values and post them on Table 6-5.

d. Using the complex factor overlay, the surface materials overlay and Table 6-4, determine the map units and F4 values and post them on Table 6-5.

e. Determine the surface roughness factor (F5) for each area from the surface materials overlay and post it on Table 6-5. See Figure 6-5.

<u>SOIL TYPE</u>	
<u>MAP UNIT (1ST TWO DIGITS)</u>	<u>DESCRIPTION</u>
GW	Well-graded gravels, gravel-sand mixtures, little or no fines.
GP	Poorly graded gravels or gravel-sand mixtures, little or no fines.
GM	Silty gravels, gravel-sand-silt mixtures.
GC	Clayey gravels, gravel-sand-clay mixtures.
SW	Well-graded sand, gravelly sands, little or no fines.
SP	Poorly graded sands or gravelly sands, little or no fines.
SM	Silty sands, sand-silt mixtures.
SC	Clayey sands, sand-clay mixtures.
ML	Inorganic silts and very fine sands, rock flour, silty or clayey fine sands or clayey silts with slight plasticity.
CL	Inorganic clays of low to medium plasticity, gravelly clays, sandy clays, silty clays, lean clays.
OL	Organic silts and organic silty clays of low plasticity.
MH	Inorganic silts, micaceous or diatomaceous fine sandy or silty soils, elastic silts.
CH	Inorganic clays of high plasticity, fat clays.
OH	Organic clays of medium to high plasticity, organic silts.
PT	Peat and other highly organic soils.
RK	Rock outcrops.
EV	Evaporites.
X	Not evaluated.
PS	Permanent snowfields.
W	Open water.

Figure 6-5. Surface materials legend

SURFACE ROUGHNESSESTIMATED SURFACE ROUGHNESS FACTORS *

MAP UNIT (3RD DIGIT)	DESCRIPTION	MEDIUM & LARGE TANKS	LARGE WHEELED VEHICLES	SMALL WHEELED VEHICLES	SMALL TRACKED VEHICLES	FOOT TROOPS
0	No Data	—	—	—	—	—
1	No surface roughness effect	1.00	1.00	1.00	1.00	1.00
2	Area of high landslide potential	.00	.00	.00	.00	.00
3	Stony soil with scattered surface rock	.90	.90	.80	.85	.95
4	Quarry	.05	.05	.05	.05	.75

* Surface roughness factors are indicated with 0.00 having maximum and 1.00 having least impact on CCM.

SOIL DEPTHS

———— <.5 meters

SOIL MOISTURE

----- Soil normally moist

..... Soil normally wet

Example: Map unit SC3 = Clayey sands, sand-clay mixtures, stony with scattered surface rock, normally moist, depth <.5 meters

Figure 6-5 continued. Surface materials legend

f. Calculate the final CCM dry and/or wet speeds for each area. Use Table 6-7 and the following formula:

$$\text{Speed (kph)} = F1/2 \times F3 \times F4W \times F5$$

Note: Round all interim and final calculations to the nearest hundredth. Post them on Table 6-5.

g. Determine the CCM dry and/or wet map unit for each area using the CCM legend, and post it on Table 6-5.

h. Combining areas of like CCM map units, draw the CCM product in final format.

i. Add the appropriate linear obstacle data.

PERFORM AVENUE OF APPROACH SYNTHESIS PROCEDURE

An avenue of approach is a route that must offer some ease of movement plus provide for an adequate dispersion of a friendly or enemy force large enough to have a significant impact on a military operation. The avenue of approach product does not include the status or possible actions of an enemy force. The end results are avenues of approach suitable for friendly force configurations capable of successfully completing the mission.

Step 1. Combine and analyze previously completed terrain products such as the CCM, transportation (LOC), and linear obstacle overlays and updated aerial photography of the area of operations to produce mobility corridors.

Step 2. Incorporate the limitations imposed by the battlefield terrain on friendly and enemy doctrine.

Step 3. Forward the data gathered in Steps 1 and 2 to G2 or S2 military intelligence (MI) personnel to identify the terrain influence on the configuration of friendly and enemy forces in the area of operations. MI personnel will evaluate mobility corridors using the doctrinal template, which considers battle doctrine, the tactical situation, and possible high-value targets.

Line of Site and Zone of Entry

Chapter 7

LINE OF SITE

The line of site (LOS) is an unobstructed view from point A to point B. Requests for LOS products are becoming more frequent just as the effective ranges of our weapons, radar, and communications equipment are increasing. We can only realize the effectiveness of long-range weapons with ranges of over 4,000 meters and of current corps and division communications equipment with ranges of 50 to 60 kilometers if the equipment is emplaced properly in areas containing equivalent-distance LOSs or groups of LOSs (as in fields of fire).

The seven methods for determining LOS are--

- Ground truth (occupy positions), which is the most reliable, least likely, and least convenient method.
- Elevation layer tints, which do not consider refraction or the curvature of the earth.
- Survey intervisibility formula, which adds constants for curvature of the earth and refraction but does not consider vegetation height.
- Analytical Photogrammetric Positioning System (APPS), which is only as good as equipment accessibility, operator training, and data-base accuracy.
- Profile (topographic map) method is the old, faithful method, almost universally known, but which does not consider refraction or curvature of the earth.
- Aerial photography (the floating line method), which is better used for short distances.
- MICROFIX, which is accurate, dependent on access to digital terrain elevation data (DTED), and useful for a wide variety of product.

As a terrain analyst, you must often determine if one location can be seen from another location or if terrain is blocking the view. Intervisibility is the ability to see from one object or station to another and is important to determine LOS. It can

be a tactical means of identifying defiladed areas for maneuver units or effects of direct fire on ground forces. The best way to determine intervisibility is to physically occupy each station. Since you cannot always be in the physical area, however, you must use topographic maps and aerial photographs. You must be able to plot coordinates on stereo-paired photos and construct a profile of a topographic-map area.

Topographic Map Method

Make sure you have your photo interpretation kit. It contains a photo plot, your remote-sensed imagery (RSI), straightedge, pin vise and pin, point designation grid (PDG) template, and a mission directive that contains location instructions.

Step 1. Look at your mission directive to obtain information about the location you will profile. The directive will also tell you which points to plot on the map. Use the UTM coordinates on the map to plot the two points.

Step 2. Draw a line across the area to be profiled connecting the two points you have just plotted. This is the profile line. Figure 7-1 shows an example.

Figure 7-1. Topographic map example

Step 3. Increase the value of the highest contour line. This will become the upper-line measurement on the numbered profile lines. Start by looking at the map and identifying the highest contour line that either crosses or touches the profile line you have just drawn. Next, look at the bottom of your map and identify the contour interval; for example, it may say “contour interval 20 meters.” Increase the highest contour line by the contour interval. For example:

Highest contour line = 200 meters
Contour interval = 20 meters
 $200 + 20 = 220$ meters

Step 4. Decrease the value of the lowest contour line that touches or crosses the profile line. This will become the lowest line measurement on the numbered profile lines. Again, use the contour interval from the map. Decrease the lowest contour line by the contour interval. For example:

Lowest contour line = 80 meters
Contour interval = 20 meters
 $80 - 20 = 60$ meters

Step 5. Prepare a profile. A profile is a side view of terrain along a line between two points. On a blank sheet of paper, draw a straight line the same length as the profile line paper. Each line represents a contour value line that crosses or touches the parallel line. The highest elevation is at the top, the lowest is at the bottom. Draw two additional lines at the top and bottom so that one line is above the highest elevation and the other is below the lowest elevation. Number all lines to the right or left in sequence, with the highest value at the top. The dotted lines at 220 and 60 are the two added lines.

Next, place your lined sheet of paper against the profile line on the map. Extend dotted, vertical (perpendicular) lines from every point on the profile line to the corresponding value line. Place a tick mark where each perpendicular line crosses the profile line. This will ensure the contour value for each profile below a map. Look at the perpendicular extensions from the contour lines to the corresponding value line.

Step 6. Interpolate hill and valley lines. Interpolation is a method of determining the highest elevation of a hill and the lowest point of a valley. Since they are either higher or lower than the known elevations, determine them separately. On the profile, insert the interpolated lines between the other contour-value lines.

To estimate the height of a hill using the interpolation method, add half the contour interval to the known elevation. For example:

Known elevation = 200 meters
Contour interval = 20 meters
 $1/2$ Contour interval = 10 meters
 $200 + 10 = 210$ meters
Interpolated value = 210 meters

To estimate the bottom of a valley using the interpolation method, subtract half the contour interval from the known elevation. For example:

Known elevation = 80 meters
Contour interval = 20 meters
1/2 Contour interval = 10 meters
 $80 - 10 = 70$ meters
Interpolated value = 70 meters

Step 7. Draw interpolated perpendicular lines extending to the corresponding value lines. Notice how close they are to the highest and lowest elevation lines.

Step 8. Draw a dark line connecting the perpendicular lines. Smooth, natural lines represent hills and valleys. V- or U-shaped lines represent streams. Figure 7-1 illustrates a completed profile.

Aerial Photography Method

Step 1. Orient the aerial photos for stereo viewing. Ensure that shadows of features such as bridges, riverbanks, and low buildings appear to fall toward you, the viewer.

Step 2. Locate the PDG coordinates on each photo. PDG coordinates provide a means of locating (plotting) points that represent features, targets, and positions on an aerial photograph. Look in your mission directive to identify the PDG coordinates of two points for each photograph. Place a grid over each photo, beginning with the left one, and locate the grid square containing the point you will plot. Using the standard “read right and up,” plot each point according to its PDG coordinates. Use the standard map scale of 1:25,000, so you can use a map protractor for plotting. Plot the points in order of the first point on the left photo, first point on the right photo, second point on the left photo, and second point on the right photo. Finally, enter the coordinates in the marginal information area on each photo.

Step 3. Pinprick the points on the photos, in the same order as in step 2.

Step 4. Draw a connecting line between the points you have pin pricked and connect points 1 and 3 on the left photograph. Next, connect points 2 and 4 on the right photo. At this time, take a moment to check your work to make sure it is accurate. The points you have plotted must correspond to the location in the mission directive.

Step 5. Place the stereoscope over the aerial photographs, with the left lens placed over the left photo and the right lens over the right photo. Look through the stereoscope and adjust the photographs slightly so you will get the best possible stereo images. Features will appear to be three-dimensional if you have obtained stereovision.

Step 6. Determine intervisibility. After positioning the stereoscope over the photos, look through your stereoscope. The two lines will fuse into one line. If it appears to float above the ground, you have determined intervisibility. If the line appears to cut through the ground, you have not. By determining intervisibility between two points, you have also determined LOS between them.

ZONE OF ENTRY

Categories

A zone of entry (ZOE) is any area in which forces, supplies, or equipment can be placed within reach of an objective area. In most situations, it may also be a zone of exit. Be prepared to show good exit zones from each ZOE, as exit zones play a key role in the selection of ZOE. Types of ZOE are existing airfields, air landing zones (ALZs), helicopter landing zones (HLZs), paratroop/resupply drop zones (RDZs), ports, and amphibious landing beaches.

The three considerations of ZOE are customers, terrain, and climate. Customer consideration includes unit type and size, movement plans, and equipment type, size, and loads. Terrain consideration includes vegetation, slope, surface materials, obstacles, and surface drainage. Climatic considerations include temperature, air density, air pressure, wind, speed, and visibility. See Figure 7-2 for potential obstacles.

Airfields

POTENTIAL OBSTACLES FOR ENTRY ZONES		
Ditches	Tree stumps	Cuts and fills
Embankments	Stone walls	Hedge rows
Large rocks	Bushes	Scattered trees
Boulders	Buildings	Barbed wire fences
Wood fences	Minefields	Cemeteries
Quarries	Levees	Karst topography
Ruins	Towers	Overhead power lines
Rice paddy dikes		Overhead telephone lines

Figure 7-2. Potential obstacles for entry zones

Description

You can select existing airfields as potential ZOE if they meet the minimum size requirement dependent on the type of aircraft to be used. The easiest way to show an existing airfield on a ZOE overlay is to use the same symbol that is used on the transportation overlay, so the customer will know the runway length, width, orientation, and pavement status.

Criteria

Airfields should accommodate the maximum size aircraft, have airfield facilities, and be in correct orientation to the map scale. See Chapter 2 for information concerning the elements of an airfield. See Figures 7-3, 7-4, 7-5.

Figure 7-3. Airfield data

Aircraft	Overall dimensions (ft)			Weight (1000 lbs)		Takeoff (ft)*	
	Length	Width	Height	Basic	Maximum takeoff	Ground run	To clear 50 ft
OV-1B	41.7	48.0	13.0	10.98	15.79	1410	2185
OV-1C	41.0	42.0	13.0	10.01	14.82	1440	2230
OV-1D	41.3	48.0	12.7	15.50	17.50	1650	2280
U-8D	31.5	45.3	11.6	4.99	7.30	1455	2400
U-8F	33.3	45.9	14.2	5.49	7.70	1065	1660

Figure 7-5. Minimum airfield requirements

Air Landing Zones

Description

ALZs are entry zones used by fixed-wing aircraft to access objective areas. They can include beaches, dry lake beds, sections of highway, and other areas that meet the criteria. Areas are classified as hasty or deliberate based on the anticipated type of missions or load requirements in a given area within the theater of operations. Hasty ALZs are unimproved surfaces good only for marginal weather operations and are unusable during prolonged periods of poor weather. Deliberate ALZs have all-weather capability and are usually permanent installations with control towers, runways, and taxiways. Deliberate classifications meet existing airfield criteria.

Figure 7-6 shows symbols for ALZ criteria. See TM 5-330 and FM 100-27 for specific information.

Criteria

- Undissected
- % Slope - per 100-foot horizontal distance
- No obstructions within glide angle of ALZ
- Oriented with prevailing winds
- Suitable Surface Materials and Surface Roughness

Figure 7-6. Air landing zone symbol

Procedures

Refer to FM 5-330 to determine proper values, then use the following formula to compute ALZ length:

$$\text{ALZ Length} = \text{TGR} + \text{ALT Cor} + \text{Temp Cor} \times \text{SF} + \text{Slope Cor}$$

Round Up.

Note: Round up the final ground run length to the next highest 100 foot value.

Example. ALZ length of 3,120 feet is rounded up to 3,200 feet.

Where:

TGR = Takeoff ground run at mean sea level and 59°F.

ALT Cor = Pressure altitude correction.

Add the dh value of entry zone based on FM 5-330 to the altitude of the entry zone, then increase the TGR by 10 percent for each 1,000-foot increase in altitude.

Temp Cor = Temperature correction. If the corrected ground run obtained in the previous computation is 5,000 feet or greater, increase the ground run by 7 percent for each increase in temperature above 59°F; if less than 5,000 feet, increase by 4 percent per 10° above 59°F. If the temperature is less than 59°F, no correction is required.

SF = Safety factor. Multiply the corrected ground run obtained in the previous computation by 1.5 for rear- area ALZs and 1.25 for support, forward, and battle area airfields.

Cor = Effective gradient correction. Increase the corrected ground run obtained in the previous computation by 8 percent for each 1 percent of effective gradient over 2 percent.

Round up = Round the final ground run length up to the next larger 100 feet.

Compare the final ALZ length and width to the minimum runway length and width shown in TM 5-330 and use the larger of the two lengths and widths.

Helicopter Landing Zones (HLZs)

HLZs are entry zones in which helicopters access an objective area. They are terrain and climate dependent. Even under the best weather conditions, using a vertical approach and departure, the helicopter requires flat and obstacle-free open areas and a surface material that will support the heavy loads of the aircraft. The load factor, elevation, and air temperature determine whether the helicopter can take off and land vertically. Helicopter approach and departure angles that are not vertical require longer distances to clear obstacles surrounding the edges of the entry zone.

Criteria

- Undissected
- Less than 15 percent slope (See FM 90-4)
- Minimum size should be based on METT-T (20 - 75m guide, minimum distance for a single helicopter)
- No vertical or ground obstructions greater than or equal to 18 inches
- 10:1 obstacle clearance ratio
- No dust, debris, or loose snow near LOC
- Stable soils

Figure 7-7.
Helicopter landing

Use the following formula to compute the size of the HLZ during daylight:

$$LS = \frac{2(RTZ + HO)}{\tan DA}$$

Where: LS = diameter of helicopter site

2 = safety factor

RTZ = radius of touch zone

HO = height of obstacle

DA = tangent of departure or approach angle in degrees, whichever is smaller

Compare the final HLZ length and width to the minimum length and width shown in FM 5-35. See Figures 7-8 and 7-9.

Use the following formula during hours of darkness:

$$LS (\text{Daylight}) \times 1.43 = LS (\text{Darkness})$$

Helicopter	Overall dimensions (ft)			Weight (1000 lbs)		Takeoff (ft)*	
	Length	Width	Height	Basic	Takeoff	Ground run	To clear 50 ft
OH-6A	30.30	26.30	8.20	1.16	2.70	0	0

Figure 7-9. Minimum helipad and heliport requirements

Figure 7-10. Drop zone symbol

DZs are entry zones in which troops or materials are delivered by parachute within a close proximity of an objective area. They are sometimes called resupply drop zones, when supplies are delivered to troops.

Criteria

- Undissected
- Less than 10 percent slope is preferred, 30 percent is allowable for supply drops
- Within 30km of a key city
- DZ near LOC
- No instructions within 1km
- Must have routes of entry or exit
- DZ has accessible cover and concealment
- Minimum width and length is dependent on the type, formation and speed of the aircraft, surface winds, the number of personnel or type of cargo being dropped, and visibility.
- For more information see FM 100-27.

Ports

Description

Ports may be used as entry zones when ships deliver troops and equipment close to the objective area. The selection of a port as an entry zone is based on geographic location, climatic conditions, and existing port facilities. Considerations include

PORT CATEGORIES			
Category	Vessel	Water depth	Other
Deep draft*	Naval	10 meters	
	Container	10-15 meters	
	Bulk carrier	12-18 meters	
	Tankers	10-28 meters	
Shallow draft**	Lash	2 meters	2 meters
	Seabee	3.4 meters	31 meters
	Barge	38 meters	38 meters
*Each vessel hatch requires 30 meters of wharf space, with the wharf at least 30 meters wide.			
** The wharf length must be 12 meters.			

Figure 7-11. Port categories

basin protection, bottom condition, shore area, communications, and water depth.

Port categories are deep draft, which includes ocean-going vessels, and shallow draft, which includes lighters, barges, and landing craft. See Figure 7-11.

Figure 7-12. Port symbol

Criteria

- Water depth greater than 2 meters
- Minimum length 30 meters per hatch
- Exit route to Main Supply Route (MSR)
- Near LOC
- Near facilities

DMA Pub 150 lists ports worldwide. See also FM 5-35.

Amphibious Landing Beaches

Amphibious landing beaches are entry zones in which troops and equipment are involved in a transition from seaborne to a land attack force within a close proximity to the objective area. The criteria used for determining the location of an amphibious landing zone is based on geographic and climatic conditions at the entry zone. However, due to the transition from sea to land, the geographic conditions are divided into two areas: conditions of the terrain at the entry zone and hydrographic conditions at the entry zones. Additional considerations include weather, extent, depth, and bottom of the sea area, beach approach, beach gradient, and hinterland (depth, concealment and transportation net).

Criteria

- Underwater gradient 30:1
- Lack of underwater obstacles
- Firm bottom
- Trafficable soils exit
- Tide information
- Open, straight-shot of beach -no enemy salients

Figure 7-13.
Landing beach
symbol

SYNTHESIS PROCEDURES

Step 1. Review requirements to determine the type and criteria of the ZOE for the projected area.

Step 2. Obtain source material, including base topographic map, aerial photography, and the vegetation, surface configuration, surface materials, obstacles, surface drainage, and transportation factor overlays.

Step 3. From the vegetation-factor overlay, extinct the following No-Go area:

- All built-up areas
- Vegetation categories A2, A3, B1, B2, C1-C4, D1-D4, E1-E4, F, I, J, K, L, M
- Agriculture (A1) that includes bamboo, rice fields, and vineyards.

Step 4. From the surface-configuration-factor overlay extract the following No-Go areas:

- Any slope greater than 2 percent for ALZs
- Any slope greater than 15 percent for HLZs
- Any slope greater than 30 percent for DZs

Step 5. From the surface-materials-factor overlay extract the following nonacceptable soil types:

- Permanent snowfields
- Peat bogs

- Rock outcrops
- Permanent wet soils
- Surface roughness with a category of 3 or 4

Soil is probably not as important a factor as vegetation or slope. However, powdery, dry soil in arid climates must be considered an impediment to helicopter landing because of the reduced visibility, possible clogging of engine intakes, and revealed helicopter location due to generation of dust plume. Very wet or mucky soil may cause the helicopter wheels to settle into the soil to such an extent as to prevent the accomplishment of the mission. Thus, soil conditions can be dangerous to a helicopter and should always be considered when selecting a landing zone site.

Surface roughness affecting helicopter landing can include rocks, ridges, domes, and sandbars. Skilled terrain analysts must determine surface roughness, visualizing the landform and making decisions concerning surface irregularities. For example, some landforms of glacial origin commonly contain potential obstacles such as boulders that are not mapped topographically and may be too small to be seen on some aerial photography.

Step 6. From the obstacle-factor overlay, extract all obstacles that are within the project area.

The two types of obstacles associated with helicopter landing zone sites are vertical obstacles, which affect helicopter approach to and departure from a landing site, and ground obstacles within the landing site such as rocks, stumps, and holes. Approach and departure obstacles include power lines, transmission towers, and chimneys. These obstacles appear on standard 1:50,000-scale topographic maps from which you can compile a factor overlay. Obstacles within the landing site may not be detected easily. You must rely on ground reconnaissance, low-altitude photography, or local geographic literature.

Step 7. From the transportation-factor overlay, extract all existing airfields that meet the criteria for ZOE's.

Step 8. Evaluate all open areas and select the ZOE's needed for the projected area. If available, evaluate the areas against the CCMs and LOCs of the area.

The criteria for minimum-size requirements depends on a number of factors, including the type and number of aircraft, supplies, or troops to land in the ZOE, temperature, wind, altitude, and geographic location. Therefore, use the criteria listed for minimum areas as a guide and revise it as needed.

Figure 8-1. Example for map overlay

Vertical Photography

Chapter 9

Vertical photography is the process and the product of aerial photography taken with the axis of the camera held in a truly vertical position. If the vertical photography is taken over flat terrain, measured distances and directions may approach the accuracy of a line on a map. Procedures for determining measurements for vertical photography follow.

SCALE DETERMINATION

The linear scale is the relationship between distance on a map or photo and the actual ground distance. Scale is expressed as a representative fraction (RF). RF may be determined by one of three basic formulas:

$$RF = \frac{f}{H} \text{ or } \frac{f}{H-h} \quad RF = \frac{PD}{GD} \quad RF = \frac{P}{MD \times MSR}$$

Where--

- RF= The representative fraction or the scale of the imagery
- f = The focal length of the camera
- H= Height of aircraft above sea level
- h = average terrain height above sea level
- PD = Photo distance on picture
- GD = Actual ground distance
- MD= Distance on map
- MSR = Map scale reciprocal

Example: Find the RF of a photo where f equals 6 inches and H equals 5,000 feet.

$$RF = \frac{f}{H}$$

$$RF = \frac{6 \text{ in}}{5,000 \text{ ft}}$$

$$RF = 1: 10,000$$

GROUND DISTANCE DETERMINATION

You must know the photo representative fraction (PRF) or the map representative fraction (MRF) to use the MSR or the PSR ground distance determination. To

determine the actual distance or size of an object on an aerial photograph or map, use one of two formulas:

$$GD = PD \times PSR \text{ or } GD = MD \times MSR$$

Where--

GD = Ground distance
 PD = Photo distance
 MD = Map distance
 PSR = Photo scale reciprocal
 MSR = Map scale reciprocal

Example Find the GD covered by a photo where the PD = 0.026 feet and PRF = 1:8800.

$$\begin{aligned} GD &= PD \times PSR \\ GD &= 0.026 \text{ feet} \times 8800 \text{ feet} \\ GD &= 228.8 \text{ feet} \end{aligned}$$

PLOTTING TEMPLATE ADJUSTMENT

The plotting template is an adjustable instrument used for plotting vertical aerial photographs. The four sides of the template are graduated in inches and five hundredths of inches and may readjusted to any combination of lengths and widths from 0.05 inches by 0.05 inches to 5.0 inches by 5.0 inches. You can adjust the template during inspection or with the formula--

Where--

TS = Template setting in inches
 PS = Photo side (in inches)
 PSR = Photo scale reciprocal
 MSR = Map scale reciprocals

Example Find the TS of a photo where PS equals 9 inches by 9 inches, PRF equals 1:5000, and MRF equals 1:25,000.

$$\begin{aligned} TS &= \frac{PS \text{ (inches)} \times PSR}{MSR} \\ TS &= \frac{9 \text{ inches} \times 5,000}{25,000} \\ TS &= 1.8 \text{ inches} \times 1.8 \text{ inches} \end{aligned}$$

PROPORTIONAL DIVIDERS USE

The proportional divider is an adjustable, compass-like instrument designed especially for enlarging or proportionally reducing drawings and sketches. Use the formula---

$$\text{scale ratio} = \frac{MSR}{PSR} \text{ or } \frac{PSR}{MSR}$$

Where--

scale ratio = Proportional divider setting
 MSR = Map scale reciprocal
 PSR = Photo scale reciprocal

Example Find the scale ratio when MRF equals 1:25,000 and PRF equals 1:5,000.

$$\begin{aligned} \text{scale ratio} &= \frac{MSR}{PSR} \\ \text{scale ratio} &= \frac{25,000}{5,000} \\ \text{scale ratio} &= 5:1 \end{aligned}$$

PHOTO COVERAGE

Photo coverage is the ground area captured on any photo. It may be expressed in square feet, square yards, or square miles. You can determine photo coverage by using the formula--

$$PSC = PSR \times PS$$

Where--

PSC = Photo side coverage on the ground
 PSR = Photo scale reciprocal
 PS = Photo side

Example Find the ground distance covered by each side of a photo with RF equals 1:10,000 and photo format equals 9 inches by 9 inches.

$$\begin{aligned} PSC &= PSR \times PS \\ PSC &= 10,000 \times 9 \text{ inches} \\ PSC &= 10,000 \times 0.75 \text{ feet} \\ PSC &= 7,500 \text{ feet} \end{aligned}$$

The total ground area covered by this photo is 7,500 feet by 7,500 feet or 56,250,000 square feet.

PHOTO COVERAGE FOR A SPECIFIC AREA

The photo coverage for a specific area refers to the number of photos required to cover a predetermined area at a desired scale and format size. You must know--

- The desired scale of the photography.
- The photo format.
- The size of the area to be covered.
- The percentage of forward overlap between photos.
- The percentage of side lap between flight lines.

Example Determine the number of photos required to cover an area 36,000 feet by 30,000 feet.

Where--
 Photo format = 9 inches by 9 inches
 Desired scale = 1:5,000
 Forward overlap = 60 percent
 Sidelap = 40 percent

Step 1. Determine the ground-area coverage of a single photo.

$$\begin{aligned} \text{Area coverage} &= \text{format} \times PSR \\ \text{Area coverage} &= .75 \text{ feet} \times 5,000 \\ \text{Area coverage} &= 3,750 \text{ feet} \times 3,750 \text{ feet} \end{aligned}$$

Step 2. Determine the amount of ground gained forward (Ggf).

$$\begin{aligned} \text{Ggf} &= \text{Total area coverage minus forward overlap percentage} \\ \text{Ggf} &= 3,750 \text{ feet} \times 40\% \\ \text{Ggf} &= 1,500 \text{ feet} \end{aligned}$$

Step 3. Determine the amount of ground gained sideways (Ggs).

$$\begin{aligned} \text{Ggs} &= \text{Total area coverage minus sidelap} \\ &\quad \text{percentage} \\ \text{Ggs} &= 3,750 \text{ feet} \times 60\% \\ \text{Ggs} &= 2,250 \text{ feet} \end{aligned}$$

Step 4. Determine the minimum number of photos per flight line.

$$\begin{aligned} \text{Photo per flight line} &= \frac{\text{length of area}}{\text{Ggf}} \\ \text{Photo per flight line} &= \frac{36,000\text{ft}}{1,500\text{ft}} \\ \text{Photo per flight line} &= 34 \end{aligned}$$

Step 5. Round off photos per flight line to the next higher number when an uneven number exists. Add two photos to each end of the flight line to ensure complete stereo coverage.

Step 6. Determine the number of flight lines.

$$\begin{aligned} \text{Flight lines} &= \frac{\text{Area width}}{\text{Ggs}} \\ \text{Flight lines} &= \frac{30,000}{2,250} \\ \text{Flight lines} &= 13 + \end{aligned}$$

Step 7. Round off the number of flight lines to next higher number when an uneven number exists.

$$13+ = 14 \text{ flight lines}$$

Step 8. Multiply the number of photos per flight line by the number of flight lines to get the total number of photos required to complete the mission.

$$14 \times 38 = 532 \text{ Photos required}$$

HEIGHT DETERMINATION

Parallax Method

When you photograph a tall object from the air in two successive exposures, the position of the point between the two photos appears to change. This displacement is called parallax, which you can measure to determine the height of an object or the elevation of a point, using two overlapping vertical photos and taking measurements in a prescribed manner. This is the most accurate method of measuring height.

Step 1. Attach the parallax bar to the cross member of the stereoscope legs with the gage to the right. Push the ends of the bar down to engage the spring clips. Slide the bar as close to you as the stereoscope legs will permit. This will place the dots directly below the stereoscope lens. (See Figure 9-1.)

Step 2. The stereometer is a stereoscope with special measuring attachments. Under each lens is a glass plate that rests on its respective photograph of a stereoscopic pair. On the bottom of each glass plate is a small dot. The dot under the left lens remains in a fixed position. You can move the dot under the right lens by an adjusting knob along the eye base of the stereometer. The movement of the

Figure 9-1 Stereoscope

right dot is measured by a micrometer dial. The range of distance between the dots is significant. For example, when you turn the adjusting knob on a stereometer so that the dots are at minimum separation, they may be 60 millimeters apart. When you turn the adjusting knob so that the dots are at a maximum separation, they may be 70 millimeters apart.

Corresponding points on two photographs must be between 60 and 70 millimeters apart when the photographs are properly oriented for stereoscopic vision. Relative to the graduation of the instrument the numbers may increase or decrease in magnitude when the dots converge. For example, if there is a range of 10 millimeters between minimum and maximum separation of the dots, the readings may be 0 at minimum and 10 at maximum or 0 at maximum and 10 at minimum, depending on the type of stereometer.

Step 3. Use fiducial marks to locate and mark principal points of both stereo paired photographs. Both photos have their own principal points but also contain the principal point of the adjacent photo in the aircraft flight line. To locate these points, transfer them from one adjacent photo to another with a stereoscope. Orient the photos for stereo viewing, locate the marked principal point, and mark the same point on the adjacent photograph. Repeat this procedure with the other photo. Each photo now has a principal point and a transferred principal point (see Figure 9-2).

Figure 9-2 Point Transfer

Figure 9-3 Flight Line

Now you can establish the flight line by drawing a line from the principal point to the transferred principal point on each photograph (see Figure 9-3). Measure the distance from the principal point to the transferred principal point (see Figure 9-4). Average these measurements using the formula--

$$b_m = \frac{b_1 + b_2}{2}$$

Where--

b_m = base means
 b_1 = measurement from the principal point to the transferred principal point on photo #1
 b_2 = measurement from the principal point to the transferred principal point on photo #2

Figure 9-4 Point Measurement

Step 4. Locate the feature that you will measure using the stereoscope and stereometer. Measure the top of the feature first to obtain the first parallax measurement p_1 . Then measure the bottom of the feature to obtain the second parallax measurement, p_2 . To obtain a parallax measurement, you must place the photos so you can see them in stereo. With the stereometer attached to the stereoscope, you can see a left and right dot through the eyepieces. Place the left dot on the point to be measured, then rotate the micrometer knob until the right dot fuses with the left dot. Record the micrometer reading as shown on the scale.

After you have taken both parallax measurements (p_1 and p_2), find the differential parallax (Δp) to help determine the height of the feature, using the equation below. You can use p , as a function of the elevation of the feature being measured, to calculate the height of any natural or manmade object.

$$\Delta p = p_1 - p_2$$

Step 5. Since all elevations are relative to each other, you must establish a reference elevation to measure height differences. This reference elevation is the average terrain elevation above mean sea level, the horizontal plane above which an aircraft photographs. You can reference the terrain elevation of certain objects shown on aerial photography from topographic maps of the same area. This data can be used to provide an estimation of the average terrain elevation (h). For parallax height determination, you must also know the altitude of the aircraft, which you can determine from the marginal information on the aerial photograph. The altitude shown on the photo is the aircraft height above mean sea level (H).

Step 6. Once you have taken all measurements from the stereo-paired photographs, you can use the parallax equation to solve height determination, as follows:

Example:

a. Determine the base means.

$$b_m = \frac{b_1 + b_2}{2}$$

$$b_m = \frac{.305' + .313'}{2}$$

$$b_m = \frac{.618'}{2}$$

$$b_m = .309'$$

b. Determine the differential parallax.

$$\Delta p = p_1 - p_2$$

$$\Delta p = .0435 \text{ feet} - .0410 \text{ feet} = .0025 \text{ feet}$$

c. Determine height.

$$\text{Height} = \frac{(H - h) \times \Delta p}{b_m + \Delta p}$$

$$\text{Height} = \frac{(5,990 \text{ ft} - 640 \text{ ft}) \times .0025 \text{ ft}}{.309 \text{ ft} + .0025 \text{ ft}}$$

$$\text{Height} = \frac{(5,350 \text{ ft}) \times .0025 \text{ ft}}{.3115 \text{ ft}}$$

$$\text{Height} = \frac{13.38 \text{ ft}^2}{.3115 \text{ ft}}$$

$$\text{Height} = 43 \text{ feet}$$

Figure 9-5 Shadow Measurement

Shadow Method

The shadow method is the least accurate of the three methods. You must have an object with a known height, and the unknown object must cast a shadow onto flat ground (see Figure 9-5). If the ground is uneven, the answer will be inaccurate. For any relatively small area of level ground, shadow length is directly proportional to object height. For example, a 40-foot tower casts a shadow twice as long as a 20-foot tower. If the shadow lengths are in a certain ratio, their photo images will be in the same ratio. To determine the height of an unknown object, measure its shadow length and multiply it by the ratio of height to shadow length established from the known object. Using the microcomparator or the photo interpreter's scale, measure the height of the unknown object and its shadow length. Place those measurements into the equation and determine the height using the following formula

Example:

$$h_k = 123 \text{ feet}$$

$$s_k = .027 \text{ feet}$$

$$s_u = .012 \text{ feet}$$

$$h_u = \frac{h_k \times s_u}{s_k}$$

$$h_u = \frac{123 \times .012'}{.027'}$$

$$h_u = 55 \text{ feet}$$

Where--

h_u = height of unknown object
 k = height of known object
 S_u = shadow length of unknown object
 S_k = shadow length of known object

Relief Displacement Method

The determination of height from relief displacement employs a single, vertical aerial photograph where both the base and the top of a vertical object are measurable. This method is particularly effective on large-scale imagery. For it to work, the displacement of the image must be visible. The formula for determining the height of an object based on its relief displacement is--

$$Hgt = \frac{\text{displacement} \times \text{flying height}}{\text{radial distance}}$$

$$Hgt = \frac{d \times (H - h)}{r}$$

Hgt = Height of the object above the average terrain elevation

H = Altitude of the aircraft above mean sea level

h = Average terrain height above mean sea level

H-h = Altitude above ground level

d = Image distance representing vertical side of the object

r = Distance between principal point and top of the object scaled from the photograph

You will first need to use a straightedge and mark the center of the photograph with fiducial marks. Always measure r from the top of the object to the center of the photograph, which you must determine by the intersection of the lines connecting the opposite fiducial marks. Measure d between the same point on the top and on the bottom of the object. The top of the object is always farther away from the center of the photograph than the bottom (see Figure 9-6). Using the photo-interpreter's scale, measure the distances and place the numbers into the equation, using procedures discussed earlier.

Figure 9-6 Displacement Measurement

Example

$$Hgt = \frac{dx(H-h)}{r}$$

$$Hgt = \frac{.017 ft \times 4,750 ft}{.261 ft} = 309 ft$$

AREA MEASUREMENT

You can use the dot grid template to measure area. Randomly place it on the lake or area to be measured. Count the dots that fall within the lake and those that fall on the line. Record the number, repeat the procedure at least three times, and determine the mean number of dots by adding the numbers together and dividing by the number of counts.

Example

First count	= 13
Second count	= 12
Third count	= 12
13+12+12	= 37
37/3	= 12.3
Mean number of dots	= 12.3

Step 1. Calculate the area in cm using the formula:

$$cm^2 = \frac{MEAN\ NUMBER\ OF\ DOTS}{25}$$

Example:

$$cm^2 = \frac{12.3}{25}$$

$$cm^2 = .49 cm^2$$

Note: Dots per cm² in this example are 25. Other dot grids are available, so check in each case to determine the dots per cm².

Step 2. Calculate the ground area using the formula--

$$Area = object\ area\ in\ cm^2 \times DRF^2$$

Example:

$$DRF = 24,000$$

$$DRF^2 = 5.76 \times 10^8$$

$$Area = (.49 cm^2 \times 5.76 \times 10^8)$$

$$Area = 2.8224 \times 10^8 cm^2$$

Where-- DRF = the denominator of the map or photo RF

Step 3. Convert the answer you obtained in Step 2 to square meters, using the formula--

$$m^2 = cm^2 \times .0001$$

$$m^2 = (2.8224 \times 10^8 cm^2) \times (.0001)$$

$$m^2 = 28,224$$

Examples:

- a. Calculate the volume of a lake which is 3 meters deep and has a surface of $28,800\text{m}^2$.

$$\text{Volume} = 28,800\text{m}^2 \times 3\text{m}$$

$$\text{Volume} = 86,400\text{m}^3$$

- b. Calculate the lake volume in gallons.

$$1\text{ m}^3 = 264.7\text{ gallons of water}$$

$$\text{Number of gallons} = (264.7\text{ gallons}/\text{m}^3) \times (86,400\text{m}^3)$$

$$\text{Number of gallons} = 22,870,080$$

QPS AREA MEASUREMENT

The QPS computes measurements automatically, greatly helping analysts find surface areas and volumes (see Figure 9-7).

Figure 9-7 QPS

When the operator moves the QPS, it measures length, area, or volume. All measurements are displayed in the proper scale and units, and analysts can print a

hard copy of the measurement results on command or automatically. The QPS is not affected by any detrimental physical condition of a map or photograph that is to be measured, such as tears, wrinkles, or folds. QPS components include--

- A calculator, which is capable of data storage and manipulation.
- A point counter, which enables automatic determination of the count total for specific features or items located on drawings, maps, and so forth.
- A planimeter, which estimates surface areas and volumes.
- A linear measuring probe, which measures lines and distances.

See TM 5-6675-324-14, TM 5-6675-325-14, and TM 5-6675-326-14 for more information on the QPS system. See Appendix C for sources of aerial and ground imagery.

Mathematical Techniques

Chapter 10

GEOMETRIC FUNCTIONS

The result of any operation performed by terrain analysts will only be as accurate as the measurements used. An interpretation and detailed analysis often requires terrain analysts to use basic geometric functions. In addition, approximation of volume, extent of stock piles, and capacity of floor space require geometric formulas. Therefore, analysts must have a sound background in the fundamentals of basic imagery math. This section serves as a guide to a unique and comprehensive collection of current geometric formulas that are basic to all types of imagery interpretation.

Determination of Area

	1. Rectangles Where-- A = Area l = Length W = Width	FORMULA: $A = l \times W$
	2. Circles Where-- A = Area d = Diameter r = Radius $\pi = 3.142$	FORMULA: $A = 2\pi r \times r$ or $\pi \times d \times r$
	3. Triangles Where-- A = Area b = Base of the triangle h = Height of the triangle	FORMULA: $A = \frac{b \times h}{2}$
	4. General quadrilaterals Where-- A = Area h ₁ = Height no. 1 h ₂ = Height no. 2 b = Base common to two triangles formed by the diagonal	FORMULA: $A = \frac{1}{2} b (h_1 + h_2)$ or $A = \frac{b (h_1 + h_2)}{2}$

Table 10-1 Area Formulas

5. Ellipses	FORMULA: $A = \pi \times a \times b$
Where--	A = Area π = 3.142 a = Semi-axis b = Semi-axis

Table 10-1 Area Formulas - continued

Determination of Volume

1. Rectangular solids	FORMULA: $V = l \times w \times h$
Where--	V = Volume l = Length w = Width h = Height
2. Cylinders	FORMULA: $V = \pi \times r^2 \times h$
Where--	V = Volume π = 3.142 r = Radius h = Height
3. Spheres	FORMULA: $V = \frac{4}{3} \pi r^3$
Where--	V = Volume π = 3.142 r = Radius 3 = Constant
4. Cones	FORMULA: $V = \frac{\pi \times r^2 \times h}{3}$
Where--	V = Volume π = 3.142 r = Radius h = Height of cone 3 = Constant
5. Triangular solids	FORMULA: $V = \frac{l \times w \times h}{2}$
Where--	V = Volume l = Length w = Width h = Height 2 = Constant

Table 10-2 Volume Formulas

6. Trapezoidal solids	FORMULA: $V = \frac{(l + l') h (w + w')}{2}$
Where--	V = Volume l = Length of base l' = Length of top w = Width of base w' = Width of top h = Height 2 = Constant
7. Irregular triangular solids	FORMULA: $V = \frac{w x h x (2a + c)}{6}$
Where--	V = Volume w = Width h = Height a = Length of base c = Length of peak 6 = Constant

Table 10-2 Volume Formulas - continued

Angle of Repose

The angle of repose of any material is the angle at which material will stand when piled. Moisture content is often the controlling factor. The percent of fine material in the mass has a decided influence on the angle, as the fine carries the bulk of the moisture. Screened material has an angle of repose of 35 to 40 degrees.

Table 10-1 gives the average angle of repose and the average weight per cubic foot of various materials of interest to the terrain analyst.

MATERIAL	ANGLE OF REPOSE (Degrees)	TAN	WEIGHT PER CUBIC FT.
sand, dry	27	0.50952	100 lbs
sand, wet	30	0.57735	115 lbs
gravel	39	0.80978	117 lbs
earth, dry	35	0.70021	90 lbs
coal, anthracite	27	0.50952	52 lbs
coal, bituminous	32	0.62487	47 lbs
coke, industrial	40	0.83910	28 lbs
iron ore, crushed	37	0.75355	145 lbs
copper ore, crushed	37	0.75355	262 lbs
limestone, crushed	37	0.75355	165 lbs

Table 10-3. Angle of Repose

Thus, knowing the angle of repose of a specific material, we can solve for height, using the horizontal dimensions.

Example: Find the height (h) of a pile of limestone.

Formula: $h = \tan A \left(\frac{1}{2}b \right)$
 $h = 0.75355 \times 20 \text{ ft.}$
 $h = 15.071 \text{ ft.}$

Where-- $b = 40 \text{ feet}$
 Angle A = 37° degrees
 $\tan 37^\circ = 0.75355$ (from Table 10-1)

TRIGONOMETRIC FUNCTIONS

Oblique photos and thermal and SLAR imagery are often used to supplement or take the place of vertical photographs. In order to ensure maximum use of this imagery, the interpreter must be familiar with certain concepts, formulas, and principles concerning their accurate interpretation. This section gives the terrain analyst a basic understanding of trigonometric functions necessary for solving problems dealing with these special types of imagery, as well as a table of trigonometric conversions.

Six Functions

To define the six trigonometric functions upon which trigonometry is based, consider the angle, initial side AQ, and terminal side AS.

Choose any point B, different from A on the terminal side AS, and drop a perpendicular BC to the initial side AQ. From the three sides (BC, AC, and AB) associated with point B, six ratios are formed which are called the six trigonometric functions of Q.

$$\frac{CB}{AB}, \frac{AC}{AB}, \frac{CB}{AC}, \frac{AB}{CB}, \frac{AB}{AC}, \text{ and } \frac{AC}{CB}$$

These ratios are independent of the position of the point B on the freed terminal side AS, for if we choose any other point B1 on AS and drop the perpendicular B1C1 to the initial side AQ, the two right triangles ABC and AB1C1 are similar. Therefore, their corresponding sides have the same ratios.

If the angle is placed in standard position on a coordinate system, and the distance AB is designated by c, the six trigonometric functions may be defined as follows:

$$\begin{aligned}\sin \text{ angle} &= \frac{CB}{AB} = \frac{\text{Opp Side}}{\text{Hyp}} = \frac{\text{Side } a}{\text{Side } b} \\ \cos \text{ angle} &= \frac{AC}{AB} = \frac{\text{Adj Side}}{\text{Hyp}} = \frac{\text{Side } b}{\text{Side } c} \\ \tan \text{ angle} &= \frac{CB}{AC} = \frac{\text{Opp Side}}{\text{Adj Side}} = \frac{\text{Side } a}{\text{Side } b} \\ \cot \text{ angle} &= \frac{AC}{CB} = \frac{\text{Adj Side}}{\text{Opp Side}} = \frac{\text{Side } b}{\text{Side } a} \\ \sec \text{ angle} &= \frac{AB}{AC} = \frac{\text{Hyp}}{\text{Adj Side}} = \frac{\text{Side } c}{\text{Side } b} \\ \csc \text{ angle} &= \frac{AB}{CB} = \frac{\text{Hyp}}{\text{Opp Side}} = \frac{\text{Side } c}{\text{Side } a}\end{aligned}$$

To define trigonometric functions of the sides of right triangles, one will often find it convenient to use the functions of an acute angle. Thus, functions of the acute angle B may be written as follows:

$$\begin{aligned}\sin \text{ angle B} &= \frac{AC}{AB} = \frac{\text{Opp Side}}{\text{Hyp}} = \frac{\text{Side } b}{\text{Side } c} \\ \cos \text{ angle B} &= \frac{BC}{AB} = \frac{\text{Adj Side}}{\text{Hyp}} = \frac{\text{Side } a}{\text{Side } c} \\ \tan \text{ angle B} &= \frac{AC}{BC} = \frac{\text{Opp Side}}{\text{Adj Side}} = \frac{\text{Side } b}{\text{Side } a} \\ \cot \text{ angle B} &= \frac{BC}{AC} = \frac{\text{Adj Side}}{\text{Opp Side}} = \frac{\text{Side } a}{\text{Side } b} \\ \sec \text{ angle B} &= \frac{AB}{BC} = \frac{\text{Hyp}}{\text{Adj Side}} = \frac{\text{Side } c}{\text{Side } a} \\ \csc \text{ angle B} &= \frac{AB}{AC} = \frac{\text{Hyp}}{\text{Opp Side}} = \frac{\text{Side } c}{\text{Side } b}\end{aligned}$$

By comparing the values of the functions of angle A and angle B, we find the following equations:

$$\begin{array}{lll}\sin A = \cos B & \tan A = \cot B & \sec A = \csc B \\ \cos A = \sin B & \cot A = \tan B & \csc A = \sec B\end{array}$$

Since angles A and B are complementary, the cosine, cotangent, and cosecant are called cofunctions of the sine, tangent and secant respectively. Conversely, we may state the following theorem: Any trigonometric function of an acute angle is equal to the corresponding cofunction of its complementary angle.

We can use this theorem to express any function of an angle greater than 45 degrees in terms of a function of an angle less than 45 degrees. For this reason, tables of values of the trigonometric functions need be computed only for angles from 0 to 45 degrees instead of from 0 to 90 degrees.

Illustrations: (a) $\sin 76^\circ 43' = \cos 90^\circ - 76^\circ 43' = \cos 13^\circ 17'$
(b) $\cot 51^\circ 28' 9'' = \tan 90^\circ - 51^\circ 28' 9'' = \tan 38^\circ 31' 51''$

Right Triangles

Terrain analysts will use the functions of the right triangle most often for interpretation purposes. In any triangle, the sum of the interior angles is 180 degrees. If the triangle to be solved is a right triangle, one of the known parts in any case is the angle C; that is, $C = 90$ degrees, and $A + B = 90$ degrees. To solve a right triangle, therefore, we must find two sides or one side and an acute angle, using the formulas--

$$A + B = 90 \text{ degrees}$$

$$\begin{aligned}\sin \text{ angle A} &= \frac{\text{Opp Side}}{\text{Hyp}} = \frac{a}{c} \\ \cos \text{ angle A} &= \frac{\text{Adj Side}}{\text{Hyp}} = \frac{b}{c} \\ \tan \text{ angle A} &= \frac{\text{Opp Side}}{\text{Adj Side}} = \frac{a}{b}\end{aligned}$$

If two sides are given, we can find the sin of angle A from the above formulas involving the two given sides. We may then use another formula to find the remaining side, and then find angle B by subtracting angle A from 90 degrees.

If one side of an acute angle is given, we begin by finding the other acute angle. Then we select one of the trigonometric formulas containing an unknown side and solve for it.

Pythagorean Theorem

The Pythagorean theorem provides a method for finding the lengths of the sides of a right triangle and checking the trigonometric method, with the statement: The square of the hypotenuse of a right triangle is equal to the sum of the squares of the other two sides. Related to a right triangle labeled A, B, and C, as shown previously and reproduced here for convenience, the theorem may be stated as the formula

$$a^2 + b^2 = c^2$$

or

$$c^2 = a^2 + b^2$$

Note: In order to solve the formula, we must understand the solution to the square root function. The square root of a number is the result of a number multiplied by itself. For example, $2 \times 2 = 4$, so the square root of 4 is 2.

To understand the interactions between weather and terrain and to work effectively with the staff weather officer (SWO), the terrain analyst must have a basic knowledge of weather phenomena and weather support procedures. This appendix discusses weather and weather-related factors that may affect military operations.

In addition to terrain, the battlefield environment includes atmosphere (weather), battle-induced contaminants (man-made weather), background signatures, and illumination (both natural and man-made). The terrain analyst, intelligence analyst, and United States Air Force weather personnel work together to integrate these environmental factors with terrain to determine their net effects on mobility and weapons usage. While weather effects on personnel and tactics are specifically an intelligence function, the same environmental phenomena also affect topographic engineer concerns. Therefore, analysis of factors should be a joint effort between topographic engineer, intelligence, and USAF weather personnel. The analyst should have a general knowledge of weather phenomena and its interaction with terrain. The analyst should also know how to get and use weather information. Since equipment and procedures change frequently, analysts should get specific information from the unit involved about effects of the weather on unit equipment and operations.

TYPES OF WEATHER INFORMATION

The three groups of weather information are observations, forecasts, and climatology. Units use observations and forecasts in support of current operations, while they use climatology for long-range planning.

Weather Observations

Weather observations are reports of actual weather conditions existing at a specific location at a given time. Observations are determined visually, with instruments, or both. Terrain analysts will base much of their analysis on current weather observations, since weather information can change very quickly. For this reason, units must also keep observations current. The SWO generally receives weather observations in codes comprised of abbreviations, numbers, letters, and symbols. Codes are used to simplify and speed transmission, not because of classification. The USAF weather personnel can explain the codes used in a given area.

The SWO can obtain observations taken by USAF weather observers, Army personnel in the Forward Area Limited Observation Program (FALOP), artillery meteorology (ARTYMET), and domestic and foreign weather services.

Unfortunately, weather observations are not always available, nor do they always contain the weather parameters of interest. However, the weather forecaster can forecast the present weather at a given location for which observations are not available. This forecast is called a "nowcast"; the complexity of the meteorological situation and the forecaster's knowledge of past conditions at that location determine its accuracy.

Weather Forecasts

SWOs usually base weather support to current operations on observed current weather and on weather forecasts. Weather forecasts are predictions of future weather for a specific period at a specific location or area. Forecast accuracy depends on the time range being forecast, the complexity of the meteorological situation, and the amount and quality of data available. Forecasts for longer time ranges are more general in nature and less accurate than those for 24 hours or less. Forecasts longer than a week are rarely very accurate because of our limited knowledge of how the weather operates. Thus, forecasters usually base long-range forecasts on climatology, a statistical summary of usual weather conditions for a given location and time of the year.

When possible, analysts should present observed weather along with forecast weather information. This lends credence to the forecast and gives the commander a sense of the reliability of the forecast. Weather forecasting is not an exact science, and not all forecasts will be accurate. The SWO will be more confident in the forecast in some situations than in others. Analysts should keep in contact with the SWO in case the forecast changes and should check the progress of the weather observations for their area of operations.

Climatology

Climate refers to the characteristic weather for a given place or area over a specified time. It is usually represented by statistics of weather conditions such as mean values, extreme values, and probability distributions. Commanders use climatology for planning upcoming operations. The SWO should have climatological information for the unit area. If not, he can get it from higher USAF channels. If the unit does not have an SWO, analysts can order climatology data directly from the Air Force under procedures in AR 115-1. Response time depends on whether the data exists and whether it exists in the format needed. Often it will be better to change the request so it can be filled with immediately available data than to demand specific computer-formulated data, which could take more time to get.

Often information from standard climatological summaries will be satisfactory, and units can get it quickly. Examples of such information include normal daily maximum and minimum surface temperatures and normal monthly rainfall amounts. If the supported unit has specific weather sensitivities not covered in standard climatological summaries, USAFETAC can formulate statistics to meet those needs. For example, if a unit has a weapon system that is limited by surface winds of 20 knots or more, the analyst can request statistics on the monthly frequencies of such winds and statistics indicating how often particular hours of the day have winds of 20 knots or more.

Two problems arise from using climatology. First, the specific information may not be available. Observations at that location may never have been taken, or the available observations may not include the specific parameter. Consequently, there is no data base upon which to formulate statistics. Units can usually overcome this shortage by the SWO or USAFETAC estimating weather conditions from nearby stations for which data is available.

Second, too much data is sometimes available. This can create a difficult situation, in which the analyst must be careful not to swamp a commander with useless statistics and unnecessary

detail. Thus, the analyst must know which weather conditions will affect the unit's operations and work with the SWO to present a concise summary of pertinent climatology.

WEATHER ELEMENTS

This section describes the application of the more common weather elements to terrain analysis. It contains the basic knowledge needed to work effectively with WETM and intelligence personnel. The information here is not complete; specific information about weather effects on the equipment used by the supported unit must come from that unit itself. Weather effects on terrain can be complex; unfortunately, few tactical decision aids are available. Until further procedures are available, much of the application of weather information will depend on the combined judgement and experience of the terrain analyst, SWO, and intelligence analyst.

Temperature

Temperature, alone or in combination with other weather elements, impacts on many activities. Extremes of temperature are a discomfort to personnel and can affect equipment and weapons systems. The difference between the temperature of a target and its background is critical to weapons using infrared sighting devices. This section outlines some factors to remember in using temperature information.

Surface temperatures in North America are generally measured in degrees Fahrenheit (°F); elsewhere they are reported in degrees Celsius (°C). Analysts always report upper air temperatures in degrees Celsius. Conversion between the two temperature scales is by the following formulas:

$$F = (9/5 \times C) + 32$$

$$C = 5/9 \times (F - 32)$$

Temperature is normally measured at about 5 feet above a grassy surface, with the thermometer shielded from direct sunlight and precipitation. This temperature is not necessarily the same as the temperature just above the surface of the ground. The temperature at grass level can be several degrees higher during the day and several degrees cooler at night. Temperature is dependent on topography, with higher elevations generally being cooler. However, since cold air is denser than warm air, cold air tends to flow into lower areas on nights with light winds.

Analysts must remember that objects are not necessarily the same temperature as the air. Metal objects exposed to sunlight, for example, tend to be hotter than air temperature, due to their absorption of solar radiation. At night they tend to be cooler than the air, because they lose their heat more rapidly by radiation. This can be very important to infrared sensing devices.

Windchill equivalent temperature (WCET), often simply called wind chill, is an approximation of the combined effect of temperature and wind on the exposed human body. Analysts must remember that the air movement causing windchill comes not only from wind but from any movement of the body relative to the air. Riding in an open truck moving at 20 mph in a 10-mph headwind gives a windchill equivalent to a 30 miles per hour wind. Windchill does not apply to equipment. For example, with a -10° F temperature, a battery will perform the same in calm conditions as in a 20-mph wind.

Frozen ground can be critical to trafficability. Frost depth depends on soil type, soil moisture content, type of ground cover, and recent temperature history at the site. Given the same soil and weather conditions, increased soil moisture (up to near the point of saturation)

will cause frost to penetrate deeper and faster. Bare soil will normally also freeze faster and deeper than sod-covered areas. Snow cover is an excellent insulator and can cause depth of frost to be shallower than in areas without snow cover. Usually, few observations of frost depth will be available. Furthermore, frost depth cannot be forecast now. Analysts will probably have to depend on their own observations of frost depth.

Temperature climatology information is usually readily available. It is important not to be misled by mean temperature information; extreme temperatures are most important. While there can be no set format for presenting temperature climatology, analysts and SWOs should consider the following example, which gives monthly data on mean daily maximums, mean daily minimums, monthly extremes, and an indication of frequency of some critical values by giving statistics of how many days those values are exceeded:

CATEGORIES*	JAN	FEB	MAR	APR	MAY	JUN	JUL	AUG	SEP	OCT	NOV	DEC
Extreme maximum	45	48	60	78	92	98	104	104	92	70	60	48
Mean daily maximum	22	32	49	60	75	92	98	98	83	64	43	33
Mean daily minimum	2	11	29	40	55	72	78	80	63	44	24	11
Extreme minimum	128	-22	-2	15	28	53	55	55	26	14	-2	-13
Number of days with temperature less than or equal to 32	31	28	23	5	2	0	0	0	4	14	24	27

* All categories are in degrees fahrenheit

Table B-1. Sample temperature data

Wind

Wind direction is always recorded as the direction *from which* the wind is blowing. Direction is in the sixteen points of the compass or in tens of degrees with north being 360°; east, 90°; south, 180°; and west, 270°. Wind speed is usually in knots (nautical miles per hour, with a nautical mile being 6,076 feet), miles per hour, or meters per second. See Appendix A for conversion tables.

A gust is a rapid fluctuation in wind speed with a variation of 10 knots or more between peak and lull. For example, if the wind were blowing out of the north northeast at a mean speed of 20 knots with gusts to 40 knots, it would be recorded as 030/20G40.

Gust spread is a measurement of wind speed fluctuation normally used only for aircraft operations. The gust spread is the instantaneous difference between peak wind speed and lull wind speed. Since the lull speed is not necessarily the same as the mean speed, the gust spread in the above example could be more than 20 knots.

Wind is highly dependent on terrain and can vary considerably over a few hundred meters. When forecasting for a large area, weather forecasters try to forecast the highest wind condition over that area. Sheltered areas will naturally experience lower wind speeds.

Analysts try to identify wind patterns not only by the general weather situation but also by any influencing terrain factors. Sea coasts and mountainous regions can have unique wind regimes. Analysts and SWOs must especially be aware of narrow mountain gaps that may funnel winds and cause locally high wind speeds.

Wind can act in combination with other weather phenomena. It raises dust which in turn reduces visibility. A very light wind can make fog more dense, but higher winds will disperse fog. Wind breaks temperature inversions. It also speeds the drying of ground and can improve trafficability.

Be careful when examining climatology of wind. Prevailing wind direction is the wind direction that predominates over a given period and is a useful statistic. However, mean wind speed over a period can be very misleading. It could be very windy during daylight hours but almost calm at night and the resulting mean wind speed would be low. However, higher wind speeds during the day could adversely affect operations. Analysts must try to get information on the frequency of occurrence of winds above the critical values for their unit.

Precipitation

Precipitation is very important to trafficability. The effect depends on the type and amount of precipitation, the soil type, surface slope, type and amount of vegetation cover, and soil moisture content before the precipitation fell. Because of this complexity, exact rules are not given. Table 6-3 lists dry and wet season rating cone indices (RCIs) for various USCS soil types. However, the decision to use dry or wet values is, at present, up to the analyst's judgement. Light showers seldom affect trafficability. They may even improve it over sand. However, moderate or greater rain will degrade it.

WETM	weather teams
WI	Wisconsin
ZOE	zone of entry

TERMS

abutment - the support at either end of a bridge.

air base - an airfield having, in addition to operational facilities, shelter for personnel and facilities for supply and repair of aircraft.

airfield - a group of facilities designed for takeoff, landing, servicing, fueling, and parking of fixed-wing and rotary-wing aircraft.

alluvium - general term for material deposited by streams, including silt, sand, gravel, clay, or boulders derived from decomposed bedrock but deposited elsewhere.

altitude - the height above an established reference base. Altitude is usually measured as height above mean sea level.

apron, cargo - a prepared area for loading and unloading personnel and cargo.

apron, maintenance - a prepared area for parking aircraft being serviced or repaired.

apron, parking - a prepared area used in place of hardstands for the parking of aircraft. It is also referred to as a conventional apron.

apron, warmup - a stabilized or surfaced area used for the assembly or warming up of aircraft, usually located at both ends of the runway adjacent to and with the long axis parallel to the connecting taxiway.

aqueduct - a large pipe or conduit made for transporting water from a distant source.

avenue of approach - route by which a force may reach an objective.

badlands - a geographical area nearly void of vegetation. An almost impassable region due to narrow avenues, sharp crests, and pinnacles.

bank - the continuous sloping margin of a stream or other water body; on a stream, designated left or right bank as it would appear to an observer facing downstream.

bar - an accumulation of alluvial material in a stream channel, commonly emergent at low water.

basalt - common name for a group of dark, fine-grained, heavy, very hard volcanic rock.

bed - the bottom on which a body of water rests.

bog - a swamp or tract of wet land commonly covered with peat.

brush - shrubs and stands of short, scrubby tree species that do not reach sufficient size for use as timber.

canal - a channel or waterway artificially constructed or maintained for conveying water or for connecting two or more bodies of water.

canopy - uppermost closed surface or roof of the forest.

channel - the trench in which a stream normally flows; that part of a body of water deep enough to be navigable.

channel cross section - a representation of a channel as it would appear if cut through crosswise and vertically at right angles to its long axis and depicting, specifically, the area of the channel through which flow has passed or is supposed to pass.

channel roughness - roughness of the channel, including extra roughness due to local expansion or contraction and obstacles, as well as roughness of the stream bed proper, such as friction offered to the flow by the surface of the bed of the channel in contact with the water; expressed by the roughness coefficient of the velocity formulas.

classification yard - a yard in which the traffic is classified in accordance with requirements and made up into trains.

clay - soil particles having diameters less than 0.0002 millimeters.

concealment - protection from observation only,

conduit - an artificial or natural channel which carries water for supply or industrial purposes.

conifer - cone bearing - trees of the "soft-wood" group such as spruce and pine. Most but not all conifers are evergreen and needle-leaved.

coniferous forest - a forest of evergreen coniferous or cone-bearing trees carrying needle-shaped leaves. Such forests have valuable softwood timber.

contamination - impairment of the quality of water to a degree which creates an actual hazard to public health by toxic chemicals, radioactive isotopes, or pathogenic organisms.

contour density - the spacing of contour lines on a map.

cover - protection from weapons fire.

cross-country movement - movement across terrain that is not specifically improved for vehicular traffic.

crown - the entire leafy part of a tree or shrub, especially as seen from above.

current velocity - the speed, expressed in units of time and distance, at which water flows in a stream, channel, or conduit.

data base - a collection of information in any form, assembled for a particular future use.

deciduous - vegetation losing all their leaves seasonally, either in the cold or dry season.

deciduous forest - a forest consisting of trees that lose their leaves at some season of the year. Such forests have valuable hardwood timber.

dendritic - a branching tree-like pattern of tributaries of a main stream.

departure yard - a yard in which trains are placed waiting departure.

diameter breast height - the diameter of a tree at 1.4m (approximately 4.5 feet) above ground level. It is abbreviated DBH.

drainage - the process of removing surface water or ground water by artificial or natural means.

engine yards or terminals - an area containing all the tracks, buildings, structures, and facilities necessary for the maintenance, care, and storage of locomotives and for providing them with all needed supplies such as fuel, water, sand and oil.

estuary - the portion of a stream valley influenced by the tide of the body of water into which it flows.

evergreen - vegetation that retains its green foliage throughout the year.

flight line - a line drawn on a map or chart to represent the flight path which an aircraft has flown when taking a series of consecutive aerial photos.

flow - a quantity of water carried by a stream or conduit, expressed in volume per unit of time.

freight terminal - the installation and facilities for handling freight business.

fiducial marks - index marks rigidly connected with the camera lens through the camera body, which form images on the negative. These marks, when intersected by a straight line drawn between opposite fiducial marks, define the principal point of the photographic print.

fuel storage area - an accessible area, having good cover, located a safe distance from troops, aircraft, and other facilities, and used for the storage and dispensing of aviation fuels.

gradient - the longitudinal slope, obtained by dividing the difference in bed or water-surface elevations.

grasslands - regions or areas where the dominant natural vegetation consists of grass.

gravel - loose, coarse, granular material larger than sand grains, resulting from breaking down of rock.

gravity yard - a yard in which the movement of cars to different sidings for sorting is accomplished by gravity alone.

hardstand - a stabilized or surfaced area provided to support standing aircraft. Hardstands are normally dispersed at intervals along each side of a taxiway.

hectare - 10,000 square meters, or 2.47 acres.

helicopter landing pad (helipad) - a prepared area on the ground designated and used only to accommodate takeoff and landing of helicopters.

heliport - a group of facilities designed for takeoff, landing, servicing, fueling, and parking of rotary-wing aircraft.

heliport landing area - a specifically prepared surface designed for rotary-wing aircraft takeoff and landing operations. It includes the paved surface (runway or landing pad) and the areas immediately adjacent thereto that have been cleared of all above-ground obstructions.

hydrology - a science dealing with the occurrence of water on the earth; its physical and chemical properties, transformations, combinations, and movements; especially with the course of water from the time of its precipitation on land until its discharge into the sea or return to the atmosphere.

index contour - contour line shown more prominently than the adjacent ones, usually every fifth one.

inland waterways - rivers, canals, lakes, and inland seas that are used as avenues of transport.

intermittent stream - a stream that flows only seasonally; one that has not cut its valley below the water table.

key terrain - any area whose seizure or control affords a marked advantage to either opposing force.

landform - the physical expression of the land surface.

lateral safety zone - an area (transitional surface) located between the runway clear area of runway edge when no clear area is provided and the clearance lines limiting the placement of building construction and other obstacles with respect to the runway centerline. The slope of the transitional surface is 7:1 outward and upward at right angles to the runway centerline.

levee - an embankment along a stream or other water body, built for the purpose of limiting floods.

line of sight - intervisibility between two points located on the earth's surface.

lines of communication - all routes--land, water, and air--that can be used by military forces in an area of operations.

local relief - the difference in elevation of the land surface.

lock - an enclosure in a canal or river with gates at each end, used in raising or lowering boats as they pass from level to level.

marsh - a tract of spongy, wet, or water-covered treeless ground usually covered by grasses, cattails, or similar vegetation.

observation - ability of force to exercise surveillance over a given area through the use of personnel or sensors.

obstacle - any object that stops, delays, or diverts movement.

outcrop - any exposure of bedrock.

overrun - a graded and compacted portion of the clear zone, located at the extension of each end of the runway to minimize risk of accident to aircraft due to overrun on takeoff or undershooting on landing. Its length is normally equal to that of the clear zone and its width is equal to that of the runway and shoulders.

parallax - the apparent displacement of the position of a feature with respect to a reference point or system caused by a shift in the point of observation.

passenger terminal - the installation and facilities for handling waiting passengers.

permeability - a rock's capacity for transmitting fluids.

photo base - the straight-line distance between the two principal points of two consecutive serial photographs.

planimeter - an instrument for measuring the area of any plane figure by passing a tracer around the boundary line.

pollution - impairment of the quality of water by biological, chemical, physical, and radioactive substances to a degree which may not create an actual hazard to public health but which does adversely and unreasonably affect such water for some beneficial uses; almost any substance becomes a pollutant if concentrated sufficiently.

pond - a small area of still water, usually artificial.

porosity - a measure of the proportion of a material consisting of pore space or voids.

profile - the bottom or water surface elevation of a stream plotted against distance.

relief - the irregularities of a land surface.

representative fraction - the ration between map or photo distance and ground distance expressed as a fraction in the same units.

reservoir - an area of water storage often artificially created by building a dam at a suitable retaining point across a watercourse.

revetment - usually a mound or wall of earth, masonry, timber, sandbags, or other suitable material erected as a protection for aircraft against small arms or artillery fire, bomb splinters, or blast.

road, access - a two-way road, normally improved, connecting the air base or airfield with the existing road system of the vicinity.

road, service - a road connecting the access road and the bomb and fuel storage areas with all hardstands and aprons for the purposes of refueling, rearming, and servicing aircraft.

running track - a track reserved for movement through a yard. Running tracks are provided for movement in either direction to enable yard engines to pass freely from one part of the yard to another.

runoff - that portion of the precipitation that is transmitted through natural surface channels; the residual of rainfall after the deduction of losses.

runway - a stabilized or surfaced rectangular area located along the centerline of the flightstrip on which aircraft normally land and take off.

sand - individual rock or mineral particles having diameters ranging from 0.5 to 2.0 millimeters.

sandstone - a sedimentary rock composed of sand-sized grains of minerals and rock fragments cemented together.

scale - the ratio between the distance on a map or photo and the corresponding distance on the ground.

sedimentation - the process by which mineral and organic matter are deposited to make sediments.

shoulder - a graded and compacted area on either side of the runway to minimize the risk of accident to aircraft running off or landing off the runway.

shrub - a low plant (not more than 5 meters high) with woody stems branching near the base.

siding - a short track connected to the main track by a switch and used for unloading, bypassing, and so forth.

silt - individual mineral particles of soil that range in size between clay and sand (0.002 m to 0.5 millimeters in diameter).

single track - a main track upon which trains are operated in both directions.

species - a kind of plant that can be distinguished from all others on the basis of inherited characteristics.

spring - a natural flow of water from the earth's surface occurring where the water table intersects the course.

sour track - a track of indefinite length diverging from a main line or track.

stand - an aggregation of trees, standing in a definite limited area.

stand density - density of stocking expressed in number of trees per hectare.

station - a place designated by name on the timetable at which a train may stop for traffic, enter or leave the main tracks, or from which fixed signals are operated.

stereoscope - a binocular instrument used for viewing in three-dimensional expressions.

storage yard - a yard in which cars are held awaiting disposition.

stream - a general term for a body of flowing water. The term is usually applied to water flowing in a natural surface channel; but it may also be applied to water flowing in an open or closed conduit and to a jet of water issuing from an opening.

swamp - a tract of wet or water-covered ground overgrown with trees and shrubs.

switch engine - an engine assigned to yard service and working within yard limits.

synthesis - the combining of elements of diverse material into a single or unified product.

takeoff ground run - the distance traveled by an aircraft along the runway before becoming airborne.

taxiway - a prepared strip for the passage of aircraft on the ground to and from the runway and parking areas. The width of the taxiway includes a stabilized, surfaced, or paved central strip.

texture - the frequency of change and arrangement of photographic tones.

touchdown area - that portion of the beginning of the runway normally used by aircraft for primary contact of wheels on landing.

tree - a woody, perennial plant with a single main stem more than 5 meters tall,

tributary - a surface or underground stream which contributes its water, either continuously or intermittently, to another and larger stream.

turbidity - the approximate amount of suspended matter in water, expressed in parts per million.

water body - an inland body of water which may or may not have a current or single direction of flow, such as a lake, reservoir, or pond.

water table - the upper surface of the zone of saturation.

watershed - the entire region that contributes water to a river or lake. Also called a drainage basin, river basin, or catchment area.

well - a deep hole or shaft sunk into the earth to tap an underground supply of water.

yard - a system of tracks provided for making up trains, storing cars, or for maintaining or repairing cars.

zone of entry - any area in which personnel, supplies, or equipment can be placed within reach of a military objective.

Abstract

Hall, Frederick C. 2001. Photo point monitoring handbook: part A—field procedures. Gen. Tech. Rep. PNW-GTR-526. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 48 p. 2 parts.

This handbook describes quick, effective methods for documenting change in vegetation and soil through repeat photography. It is published in two parts: field procedures in part A and concepts and office analysis in part B. Topics may be effects of logging, change in wildlife habitat, livestock grazing impacts, or stream channel reaction to land management. Land managers, foresters, ranchers, wildlife biologists, and land owners may find this monitoring system useful. Part A discusses three critical elements: (1) maps to find the sampling location and maps of the photo monitoring layout; (2) documentation of the monitoring system to include purpose, camera and film, weather, season, sampling system, and equipment; and (3) precise replication in the repeat photography.

Keywords: Monitoring, photography.

Preface

This handbook is a synopsis of repeat photography principles and photo point sampling from the publication *Ground Based Photographic Monitoring*, PNW-GTR-503, which is based on 45 years of experience in repeat photography by the author. During those years, many nuances were discovered that bear discussion and emphasis so that new users can avoid the pitfalls I ran into. The terms *should*, *must*, *do not*, and *will* are used to help users avoid problems and are not meant as rules.

Introduction

Anyone interested in quick and effective documentation of change in vegetation or soil through repeat photography will find this handbook useful. Illustrations cover such topics as streamside changes, riparian willow response to beavers, logging, livestock use, and mountain pine beetle (*Dendroctonus ponderosa*) kill of lodgepole pine (*Pinus contorta* var. *latifolia* Englm.). People, such as foresters, ranchers, wildlife biologists, and nature enthusiasts, interested in natural resources can establish photo point monitoring (discussed here) to appraise changes (see part B) in natural resources. No special skill or training is required other than some knowledge of cameras.

There is one essential criteria if repeat photography is used to document change. Distance from camera to photo point **must** remain the same (part B). For this reason, both the camera location and photo point require permanent markers. The system recommended is use of cheap fenceposts or steel stakes, usually ½ inch (1.2 cm) diameter concrete reinforcing bar.

This field procedure handbook is divided into several parts: basic foundations for photo monitoring, with discussions on objectives, selecting an area, techniques for general photography, procedures for specific topic pictures, shrub profile monitoring, and tree cover sampling. Use of forms in part B are illustrated.

Basics

The primary consideration in photo monitoring is an objective. Ask yourself several questions: What is the topic of this photograph? Why do I want to take this picture? What am I trying to show? What appeals to me? What will the picture demonstrate? (Hedgecoe 1994, Johnson 1991).

Photo Monitoring Objectives

Consider the five basic questions for any inquiry: why, where, what, when, and how (Borman 1995, Nader and others 1995).

Why—“Why” to monitor reveals the question or questions needing to be answered. Implementation monitoring asks **if** we did what we said, effectiveness asks if it **did** what we wanted, and validation asks if it **is** meeting the objectives. The “why” question

Figure 1—A ponderosa pine stand with pinegrass ground vegetation showing effects of logging: undisturbed in 1981, 1982 after the first selection cut, and in 1989 after the second selection cut and precommercial thinning. These views, with their dramatic differences, emphasize the need for permanent marking of both camera locations and photo points. Exact picture reorientation uses the “1M” of the meter board as the photographic center (also see fig. 18) and for focusing the camera for best depth of field at the meter board.

Figure 2—Filing system form “Camera Location and Photo Points” showing general photographs of Pole Camp taken from the witness stump: (A) the left landscape, and (B) the right landscape diagramed in figure 6. Note repeat of fenceposts 1 and 2 in both pictures. Fenceposts identify camera locations 1, 2 and 3 and photo points “D” for the dry meadow, “W” for the wet meadow, and “S” for the streambank. Photo identification cards similar to figure 10, a form from part B, appendix A, are at the bottom of each picture. The purpose of these photographs is twofold: to illustrate the general sampling area and to show location of the photo monitoring layout. Used in conjunction with the map in figure 6, someone other than the original sampling crew could find and rephotograph this site.

sets the stage for all other discussion. Is a proposed treatment to be monitored (fig. 1)? Is animal distribution to be appraised? Are things changing as a result of management decisions (Borman 1995, Nader and others 1995)?

Figure 3—A general photograph taken in 1997 at Pole Camp; the topic is streambank stability. This streambank photo point is taken upstream from camera location 2 (shown in fig. 2 and on the map in fig. 6). Fencepost 1 is camera location 1, fencepost 3 is camera location 3 looking downstream at photo point “S,” “S” is the photo point for the streambank, and fencepost “W” is the photo point for the wet meadow.

Where—“Where” to monitor depends on the “why.” How does one select representative tracts, animal activity areas, treatment sites, or particular kinds of treatments? How are number, size, and location of activities, such as fire, logging, revegetation, livestock grazing or flood, selected? Ask yourself, “Where is the best location that will answer my questions (fig. 2; Borman 1995, Nader and others 1995)?” Critical documents are a map to locate the site and a site map to document all camera locations and photo points.

What—“What” to monitor means selecting specific items (topics) on the tract to support the “why” questions: vegetation, soil, streambanks (fig. 3), or animals. Ask yourself, “What are the critical few items that must be documented? What is expected to change? What will the picture demonstrate (Borman 1995, Johnson 1991, Nader and others 1995)?” The “what” dictates the sampling layout.

Figure 4—Pole Camp “W” (wet meadow) photo point showing three dates of the same year. June 15 is before scheduled grazing, August 1 is at change in rotation pastures, and October 1 is after grazing. This pasture was rested from June 15 to August 1. October 1 illustrates the degree of livestock use on Kentucky bluegrass at the meter board, on aquatic sedge behind the board, and on willows.

When—“When” to monitor supports the “why” and “what” questions. Does it encompass a year or years? one or more times a year (fig. 4)? specific dates? specific time(s) of day (Borman 1995, Nader and others 1995)? All are important with both animal and site monitoring. Scheduling when to photograph deals with before and after treatment and how often thereafter. Unplanned disturbances, such as fire or flood, pose special problems. A monitoring protocol may have to be developed on the spot during an event to establish photo points and define a followup schedule.

How—“How” to monitor is determined by “what” as influenced by “why” and “when.” It may encompass detailed protocols for photographic procedures, which may be to obtain either qualitative data (estimates) or quantitative data (measured in the field or measured from photographs).

A simple question might deal with effects of livestock grazing on a riparian area: (1) Are streambanks being broken down? (2) Are riparian shrubs able to grow in both height and crown spread? (3) Is there enough herbage remaining after grazing to trap sediments from flooding? (4) Is herbaceous vegetation stable, improving, or deteriorating?

These questions require selection of a sampling location, placement of enough photo points to answer each of the four questions, and establishment of camera locations to adequately photograph each photo point. Try to select camera locations that will photograph more than one photo point. Next, time or times of year to do the photography must be specified, such as just prior to animal use of the area, just after they leave, or fall vegetation conditions. Will a riparian site be monitored for high spring runoff? late season low flows? or during floods? Monitoring of stream flows vs. animal use probably will require different scheduling.

Recommendation—Write down the specific objectives and protocols for each photo monitoring project. Write them so that someone other than the installer can understand the purpose, can follow the protocols, and can become enthusiastic about the project.

Selecting an Area

Selection of a monitoring area requires a great deal of professional expertise liberally mixed with artistic finesse. The **purpose** for photographic monitoring is the most critical factor in considering where to monitor (Borman 1995, Nader and others 1995): Where in the landscape is my topic of concern, and once at the area, what kind of change do I want to document? In some cases, "where" is straight forward; for example, documentation of logging impacts requires an area being logged (fig. 1), and effects of beavers on a stream requires beaver dams. On the other hand, documentation of impacts from livestock grazing requires understanding livestock distribution plus knowing the location of areas sensitive to grazing and the most critical season of use.

Once in an area, the real decisions must be made. Determine specifically what to monitor for change. Figure 2 shows two general views of Pole Camp in northeast Oregon where some examples of photo monitoring are located. The purpose was to document effects on a riparian area from livestock grazing. Pole Camp was selected because it was preferred by livestock. Specific objectives were to evaluate grazing effects on streambanks (fig. 3); willow (*Salix* spp.) shrub utilization (fig. 3); differences in use between Kentucky bluegrass (*Poa pratensis* L.) by the fencepost on the right (1) and aquatic sedge (*Carex aquatilis* Wahlenb.) at the fencepost in the left background (W). The topic in figure 3 is streambank stability.

Figure 1 is a different situation. The purpose for photo sampling was to document effects of a two-stage overstory removal and subsequent precommercial thinning on stand structure and ground vegetation. The sale area determined the site. Stand conditions of open ponderosa pine (*Pinus ponderosa* Dougl. ex Laws.) and clumped reproduction across an opening were chosen for the photo point. The opening was selected to avoid tree crown encroachment between the camera location and photo point and to appraise logging effects on livestock forage. It was photographed before and after each entry to log.

Figure 5—USDA Forest Service ranger district map showing location of the Button Meadow, Pole Camp, and Lower Emigrant riparian study sites. Road numbers, mileage from road junctions, and directions to the witness sites are given on the filing system form “Photographic Site Description and Location” (fig. 6).

After appraising the area, establish the photo monitoring system as discussed below in “General Photography” and “Topic Photography.” The sampling layout must be mapped as described next.

Locating the Monitoring System

Assume that the person installing the monitoring program will **not** be the one to find and rephotograph the area. Provide maps and instructions accordingly. A local map showing roads and the site locates Pole Camp, one of three locations for the Emigrant Creek riparian study (fig. 5).

After laying out the photography system, select a witness site to mark the area. Identify it with a permanent marker, such as an orange aluminum tag, and determine direction and measured distance to camera locations, photo points, or both. Inscribe these on the identification tag. Next map the camera locations and photo points with directions and measured distances on the filing system form “Photographic Site Description and Location” (fig. 6), found in part B, appendix A. Note whether the direction

 Discussion: Three photo points established in Oct 1974 documented
dry meadow (D), wet meadow with willows (W) and a falling block of
rock at the stream edge (S) (1997) Flood at 2/96, washed out beaver
dams & created a new channel. Shrub sampling initiated 6/97.

MAP

Use back of sheet for additional details.

Figure 6—Filing system form "Photographic Site Description and Location" showing the monitoring layout for Pole Camp. In the lower left corner is a reference to the junction of roads 43 and 4365 at 0.25 mile (0.4 km). Immediately opposite the road turnout is a lodgepole pine witness stump 28 inches (71 cm) in diameter. An aluminum tag, orange for visibility, is attached to the stump with directions and distances to camera locations. An additional map, noted by the square labeled "See detail attached," is shown in figure 17. It documents triangulation of the streambank photo point "S." Another note, "Shrub transect - see attached," refers to an installation in 1997, which is shown in figures 22, 23, and 25 dealing with shrub profile photo monitoring.

is taken in magnetic or true degrees by indicating either "M" or "T." A 21-degree deviation in the Pacific Northwest must be accounted for. Measure distances between the witness site, camera locations, and photo points on the ground. Do not attempt conversion to horizontal distance.

Fenceposts or stakes—Monitoring, by definition, means repeated observation; therefore, all camera locations and photo points must be permanently marked. The recommended method is stamped metal fenceposts shown in figures 2 and 3. In 2000, these cost about \$2.75 each for a 5-foot (1.5-m) post. Stamped metal has several advantages over strong T-bar posts: they are flimsy and will bend if driven over by a vehicle or run into by an animal; they will bend flat and remain in the ground to mark the spot; they resist theft because they are just as difficult to pull out as a good fencepost but are not worth the trouble; and they are easy to carry and pound. The primary advantage of flimsy fenceposts is their visibility, as seen in figures 2 and 3. If visibility is not desired, steel rebar stakes are a choice but require a metal detector for relocation (White's Electronics, Inc. 1996).

Steel stakes, preferably concrete reinforcing bar (rebar) have been used and may be required for shallow soils, areas that will be disturbed, or locations where fenceposts may be obtrusive. If disturbance or shallow soils prevents the use of fenceposts, stakes should be driven flush with the ground. If left a few inches above the ground, stakes will damage tires, hooves, or feet. They are always difficult to find. When driven flush with the ground, they require a metal detector for relocation (White's Electronics, Inc. 1996), but even then, the stakes must be of some mass for detection with a simple, \$250 machine. Angle iron should be 1 inch (2.5 cm) on the angle and at least 12 inches (30 cm) long. Cement reinforcing bar should be at least $\frac{3}{8}$ inch (1 cm) in diameter and at least 12 inches (30 cm) long. Shorter lengths may be needed for shallow soils.

Distance from camera to photo point—One overriding consideration in photo monitoring is to use the same distance between the camera location and photo point for all subsequent photography of that sample. Any analysis of change depicted in the photographs can be made **only** when the distance remains the same (part B). Therefore, always **measure** the distance from camera location to photo point and mark with steel fenceposts or stakes.

Figure 7—A site locator fieldbook is my system for finding camera locations and photo points. It is a pocket-sized set of photographs and directions mounted on cardboard (file separator thickness). (A) The left landscape view of the sampling area at Pole Camp shown in figure 2. (A) also locates camera locations 1, 2, and 3. Camera location 1 has two photo points: "D" is Pole Camp dry meadow and "W" is Pole Camp wet meadow (figs. 2 and 6). (B) The upstream photo point taken from camera location (2) to "S" (illustrated in fig. 3). A map of this area is shown in figure 6.

A fixed distance for all photo monitoring is not required. It may differ from one photo point to another. Camera format also may change, such as first pictures with a 50mm lens and next pictures with a 35mm lens, but distance must remain the same. It can remain the same in repeat photography only if permanently marked.

Site locator fieldbook—A photo monitoring fieldbook is recommended for carrying the original photos and some intervening photographs into the field (fig. 7). If previous photographs were done by different people, you may discover some disorientation of subsequent views. For that reason, a copy of the original photograph is very important. Rephotograph from the original and not from any misoriented intervening views.

My system for Pole Camp is depicted in figure 7. Figure 7A is a landscape view of the Pole Camp flood plain from the witness site that identifies camera locations and some photo points. It locates the left of two flood-plain scenes, both shown in figure 2 (and mapped in fig. 6). Figure 7B is a view from camera location 2 to photo point “S” on the streambank, the scene in figure 3.

The pocket-size booklet has a picture from each witness site to each camera location and photo point and includes directions from the witness site to camera location and orientation of the photo point.

Once at the area, review the photographs for changes in vegetation. Next, note the number of years since the last photograph, particularly if it was taken more than 3 years previous. The purpose is to evaluate change in the vegetation that might make previous photographs difficult to interpret (fig.1).

Relocating Photo Points

If camera locations and photo points were not marked, they may be approximated by the following triangulation procedure. Align items in the original photograph as shown in figure 8A. Start in the center of the photograph to orient the direction of the picture and draw line 1 on the photo, the photo point direction. Then, for

Text continues on page 15.

Figure 8—Photograph reorientation uses a black-and-white photo on which a triangulation system is diagrammed. A center line (1) is established on the original photograph (A) for direction. The center line is identified by position of trees in the background and framing the picture with trees in the foreground. Then positions of items 2 and 3 at the sides of the picture are used to triangulate the camera location. Looking to the right, note the position of trees at arrow 2 while also looking left for tree positions at arrow 3. For (B), the photographer moves forward and backward along the center line until items at arrow 2 and arrow 3 are aligned. Try to include some unusual object in the photograph, such as the pair of stumps in the lower right corner. Photograph (A) is preunderburn condition and (B) is postburn and salvage of killed trees. In (B), note the missing trees at arrows “a” and “b,” and a burned-out stump at arrow “c.”

Figure 9—Relocation of a historical photograph taken in 1914 of Branson Creek, Wallowa County, Oregon. Skovlin and Thomas (1995, p. 22-23) took the bottom view in 1992. On a copy of the original (1914) photo, mark orientation lines. "A" identifies the centerline orientation. Then choose objects on the edges of the picture, such as "B" and "C," to triangulate location of the original camera. Once centered on the original photograph, move forward or backward until the angles of B and C are similar to the original photograph. Slight differences in orientation lines between 1914 and 1992 suggest that in 1992, the camera was a few yards left of the original location. The usefulness of black-and-white photographs is illustrated here by being able to draw triangulation lines directly on a copy of the 1914 picture.

the camera location, find items on the sides of the picture, shown by arrows 2 and 3, to triangulate the location. The items are distances between trees. Move forward or backward along line 1 (fig. 8B) to repeat the distances shown at 2 and 3. This is the camera location and photo point direction. Mark the camera location with a fencepost and add a meter board (photo point) location 25 to 35 feet (8 to 10 m) distant.

Figure 9 applies this triangulation concept to relocation of landscape photographs.

If major vegetation manipulation has occurred as shown in figure 1, relocation may be very difficult.

When to Photograph

When to photograph is usually determined by the activity being monitored. Pole Camp, for example, is part of a study evaluating effects of cattle grazing on a riparian area. Figure 3 illustrates one topic of concern, streambank stability. Photographs have been taken three times per year to correspond with livestock activity: June 15 just before grazing, August 1 as cattle change pastures, and October 1 after animals leave the allotment (fig. 4). This three-season monitoring is repeated every year.

Figure 1 illustrates a very different monitoring schedule. Photographs were planned for the first week in August as an index to appraise vegetation development. They were taken just before logging and in each of the two seasons after cutting to document rapid changes in ground vegetation. Then a 5-year rephotography cycle was established to follow slower changes in both stand structure and ground vegetation. The routine was repeated with the second logging and the precommercial thinning.

If vegetation is a primary topic, consider establishing a fixed date or dates for rephotography. Established dates have several advantages: (1) they set a consistent reference point to evaluate seasonal differences in plant phenological development, (2) they provide a consistent reference for comparing change over several years, and (3) they establish a consistent time interval over which change is documented.

Figure 11—Filing system form “Photo Points and Close Photos” documenting a ponderosa pine/elk sedge community. This area had not been previously logged and had only sporadic sheep use because water was 1.5 miles (2.4 km) distant. The general view is followed by pictures to the left and right of the meter board. The concept is to show both a general view and a pair of closeups to document change. Figure 18 illustrates what happened in this view after logging and 18 years later. Species noted are: CAGE (*Carex geyeri* Boot.), PONE (*Poa nervosa* (Hook.) Vasey), CARO (*Carex rossii* Boot.), and FRVI (*Fragaria virginiana* Duchesne).

Photograph Identification

Each photograph should be identified by site name, photograph number, and date. Figure 10 is an example for use with general or topic photographs (fig. 2). A critical factor is identifying **negatives** for color or black-and-white pictures or digital images. The borders of slides can be written on, but there is no similar place to identify negatives or digital memory card images. Placing a photo identification card in each picture assures a permanent record on the negative or image. This—negative identification—has been one of my biggest problems. Part B, appendix A, contains blank photo identification forms (“Camera-Photo” and “Shrub Photo Sampling”), which can be copied onto medium blue colored paper.

Paper color is the next consideration. Plain white or light colors, common in the office environment, are not suitable because they are too light in color and will bleach out when photographed. The recommended paper color is either Hammermill Brite Hue Blue or Georgia Pacific Papers Hots Blue (part B, app. A). Tests have shown these darker blue hues to be superior to other intense colors such as green and yellow.

Describing the Topic

Describe what is in the photographed scene. Include plant species, ground conditions, disturbances, or any other pertinent item. Part B, appendix A, contains forms having provision for recording these notes. For example, the filing system form “Camera Location and Photo Points” is shown in figure 2 with two views of Pole Camp and brief comments about each photo. And figure 11 is the “Photo Points and Close Photos” form for a general view and two closeup photographs of a ponderosa pine/elk sedge (*Carex geyeri* Boot.) plant community in undisturbed condition. Canopy cover estimates of dominant species are recorded in each closeup photo. Other topic description forms are discussed below in “Shrub Profile Photo Monitoring” and “Tree Cover Sampling.” The forms are available in part B, appendix A.

General Photography

General photographs document a scene rather than a specific topic marked by a meter board. They are similar to landscape pictures in that they may not contain a size control board (meter

PHOTOGRAPHIC SITE DESCRIPTION AND LOCATION

Figure 13—Filing system form “Camera Location and Photo Points” documenting stand conditions in 1977, one year after mountain pine beetle attack on lodgepole pine. The needle color on trees killed in the first year changed from green to dark red (not visible here). Compare to figures 14 and 15. Photo orientation used the road center line.

Concept

In many cases, general photographs document a scene in which a meter board cannot be placed to orient and focus the camera. One use of general photographs is shown in figure 2. Filing system form “Camera Location and Photo Points” is used in two pictures of Pole Camp where fenceposts marking camera locations and photo points may be identified. Another use is illustrated in figures 13 to 15, which document effects of mountain pine beetle attacks on lodgepole pine.

Figure 15—Stand conditions in 1991, 14 years after beetle attack and 13 growing seasons since figure 13. Photo point "A" shows most dominant trees are down, which creates severe burn conditions at ground level. Photo point "B" illustrates natural regeneration height growth. Orientation of repeat general photography without a meter board requires skill and a set of orientation pictures similar to those in figure 7.

- Filing system forms "Photographic Site Description and Location" (figs. 6 and 12) and "Camera Location and Photo Points" (figs. 2 and 13-15) from part B, appendix A.
- Fenceposts and steel stakes sufficient for the number of camera locations desired. Include a pounder.
- A tripod to use for camera reorientation.

Technique

Select a scene that will meet your monitoring objectives. Describe it, including plant species, ground cover items, disturbance, or whatever the topic of the photograph is by using the filing system form “Camera Location and Photo Points.”

Photograph the scene.

Make maps of the location and layout of the scene on the filing system form “Photographic Site Description and Location” (figs. 6 and 12). In figure 6, the two photos from figure 2 are labeled “Pan Left” and “Pan Right.”

Reorientation—Reorientation of subsequent pictures is a major concern due to lack of a meter board. Identification of key items in each view will be needed. In figure 6, for example, the tall tree in the right background of picture (A) is the same tree as in the left background of picture (B). Panoramic views, such as figure 6, always should include about 10 percent overlap between photographs.

Systems used for landscape photo reorientation (discussion at fig. 8) are of major help. On a black-and-white copy of the scene, mark reorientation items as shown in figures 8 and 9. With the camera mounted on a tripod, compare the picture in hand with the scene through the camera. Orient the camera accordingly.

Figure 7 illustrates a site locator fieldbook for rephotographing general views. It has 3- by 5-inch (7.5- by 12.5-cm) photographs mounted on 5- by 5-inch (12.5- by 12.5-cm) cardboard. Instructions are given under each picture for its location and orientation. These fit into a vest pocket for use in the field. Figure 3 is a recent picture of figure 7B.

Example—Figures 13 to 15 illustrate general photography documenting effects of mountain pine beetle on lodgepole pine along highway 244 in the Blue Mountains of eastern Oregon. Figure 12 is filing system form “Photographic Site Description and Location” mapping two camera locations. Camera location 1 has two photo points (figs. 13 to 15) and camera location 2 has three photo points. Monitoring started in 1976 when beetles first attacked the stands.

Figures 13 to 15 show the use of filing system form “Camera Location and Photo Points” to document beetle effects over a 14-year period. Figure 13 depicts second-year effects of beetle attack where trees killed the first year have started to drop their needles. Figure 14 is the third year after attack and shows massive standing fuel (14A) and salvage (14B). Figure 15, 14 years after initial attack and 13 growing seasons after figure 13, illustrates tree fall (15A) and growth of natural regeneration (15B).

Topic Photography

Topic photography narrows the subject from a general view to a specific item of interest. It adds a meter board, or other size control object, to identify the photographic topic (figs. 1, 3, 4, and 11).

Concept

We will assume monitoring objectives have been established as discussed in “Basics.” A meter board, or other size control board, is placed at the selected topic for several reasons: to (1) identify the item being monitored for change; (2) establish a camera orientation reference point for subsequent photography; (3) set up a constant size-reference by which change can be documented, for example by grid analysis; and (4) provide a point on which to focus the camera for optimum depth of field.

Figure 3 illustrates identification of a very specific topic, stream-bank stability. Figure 1 deals with a general view limited to area around the meter board; the topic is effect of logging and pre-commercial thinning on stand structure and ground vegetation. Purpose of topic monitoring is the primary factor in selecting a monitoring layout.

The effect of distance from the camera to the meter board to emphasize a topic is shown in figure 16. The topic in 16A is a transect for nested frequency, in 16B it is density of grass and big sagebrush (*Artemisia tridentata* Nutt.), and in 16C it is species density and use (none in this case). Select a camera-to-photo-point distance that best depicts what you want to emphasize. Remember that once the distance is established, it **must** remain fixed.

Figure 16—Evaluation of a 35mm lens on a 35mm camera for placement of a meter board to emphasize a topic. This is a transect on the Crooked River National Grassland in eastern Oregon. (A) Placement of the meter board 33 feet (10 m) from the camera. It is essentially the same as 46 feet (14 m) distance with a 50mm lens. (B) Distance of 23 feet (7 m), essentially similar to 33 feet using a 50mm lens (fig. 31, part B). (C) Sixteen feet (5 m) distant, equivalent to 23 feet with a 50mm lens. A consistent distance between camera location and photo point for all photographs is not required. Choose a distance that best documents what you want to show. But, after your choose it, it must remain the same.

Equipment

The following equipment is required for topic photography:

1. Camera or cameras with both color and black and white film or a digital camera.
2. Form "Camera-Photo" from part B, appendix A, printed on medium blue paper.
3. Forms for site identification and photo points from part B, appendix A: "Photographic Site Description and Location" and "Camera Location and Photo Points"
4. Meter board (part B, app. B).
5. Clipboard with its support to hold the photo identification forms (part B, appendix B).
6. Fenceposts and steel stakes sufficient for the number of camera locations and photo points desired. Include a pounder.
7. Compass and 100-foot (30 m) tape for measuring distance.
8. Metal detector for locating stakes.

Technique

Several steps are needed to establish topic photo monitoring. Pole Camp (fig. 2) is used as an example.

Define the topics of interest. At Pole Camp, primary topics were effects of livestock grazing on streambank stability, differential utilization on dry and wet meadows, and impacts on willow shrubs.

Next, define what coverage is desired in the monitoring area. How many streambank sites are desired? How many dry and wet meadows and where? How many shrubs should be monitored and where are they located (see "Shrub Profile Photo Monitoring")? Notice the distribution of willow shrubs in figure 2A and the pattern of dry to moist to wet meadow in 2B.

Photo points and camera locations—Based on the desired objectives, locate photo points (meter boards) to best document change. Then establish camera locations for optimum coverage of the photo point topic. Coverage might require multiple photo

points from the same camera location or multiple camera locations focusing on the same photo point. Figure 6 maps two photo points (“D” and “W”—dry and wet meadow) from camera location 1 and two camera locations (2 and 3) focusing on photo point “S” (streambank). Figure 2 shows these camera locations and photo points. Advantages are twofold: First, relocation tends to be easier when only one point must be located that will serve two or more views, and second, one point showing several views tends to tie the sampling area together.

Riparian considerations—Riverine riparian settings have two unique photo monitoring characteristics not found in dryland situations: floods and beavers. These characteristics require some special considerations in locating both camera locations and photo points.

Camera locations should not be placed at the stream edge because they cannot be relocated if the edge erodes. Place them 3 to 5 feet (1 to 1.5 m) away from the edge and, if deemed necessary, triangulate their location (fig. 17). They should not be placed in the stream unless exact relocation for both height above the original streambed and position in the stream is assured. At times, camera locations documenting photo points in or at a stream edge may be difficult to establish.

Photo points at the stream edge may be highly desirable (figs. 3 and 17). Consider the following: (1) Use a fencepost to mark the meter board and pound it down to exactly the meter board height. This will help document erosion or deposition (fig. 3) at the base of the fencepost. When the meter board is placed for a repeat photo, measure the distance from the top of the fencepost to the top of the meter board to document the amount of change. (2) Triangulate location of the streambank fencepost (fig. 17) to assure its exact relocation should a flood remove it. If it is removed, replace the fencepost to the current meter board height. Amount of change in the meter board can be documented from an unchanged camera location only by comparing the meter board with adjacent items, such as the streambank.

Figure 17—Triangulation location of the meter board in figure 3 to document streambank erosion at Pole Camp. This map is the boxed area shown in figure 6. Any photo point or camera location in a tenuous spot should be referenced by two or more locator stakes.

Camera orientation and focus—Consistent repeat photography requires a reference point to orient subsequent views. The objective is to have the view remain constant as items within the view change. A meter board serves this purpose. Figure 18 shows three repeat photographs of a ponderosa pine/elk sedge community that was selectively cut. Figure 18A illustrates how the camera focus ring is placed over the “1M,” which accomplishes two things: (1) it provides a common orientation point for the first and subsequent photographs, and (2) it provides a

Figure 18—A meter board is used to aim the camera for consistent repeat photography. (A) Placement of the camera focus ring on the 1M," which puts the "1M" in the center of the picture (dashed lines). This orientation produces exact replication of repeat photographs as shown in (B) and (C). Focusing the camera on "1M" provides optimum sharpness and depth of field at the meter board. With an f-stop of 8, everything in the picture will be in focus. This series is part of a study following logging effects on ground vegetation and stand structure (fig. 11). (A) 1977 just before a selection cut, (B) the summer after the cut (a two-turn skid trail crossed the meter board location), and (C) 1995, 18 years later.

locus for focusing the camera for maximum depth of field. With the meter board placed at the topic of interest, the topic should always be in sharp focus.

Other options may be considered with topic photography: close-up pictures of the meter board and overhead photos of tree canopy.

Closeup photos—In many cases, details might be desired that are not accommodated by a meter board 20 to 35 feet (7 to 10 m) distant. Closeup photos, one from each side of the meter board, are recommended (fig. 19). After the general photo is taken, walk up to the meter board and photograph it on each side. With a 50mm lens, stand 7 feet (2 m) away or with a 35mm lens, stand 5 feet (1.5 m) away. Figure 19 illustrates a 50mm lens.

A critical element is to always place the top of the meter board all the way up in a corner of the view (fig. 20). Details on the ground are shown in about a 5- by 5-foot (1.5- by 1.5-m) area on each side of the meter board (figs. 19 and 20). Always take a general photo and two closeup photos to document change (fig. 11).

Figure 11 illustrates use of filing system form “Photo Points and Close Photos” (part B, app. A) for mounting and filing topic photographs. It is the 1977 view of ponderosa pine shown in figure 18.

Overhead canopy—Pictures of the overhead tree canopy may be useful when documenting changes in tree canopy cover. The technique is discussed in “Tree Cover Sampling.” A word of **caution:** camera focal length **must be the same** for all subsequent pictures because there is no size control board by which to adjust different focal length photos to the same size.

An investigator may elect to do all three kinds of photography: topic view, closeups on each side of the meter board, and an overhead view for maximum documentation of treatment effects.

Text continues on page 33.

Figure 19.—Technique for documenting ground vegetation by using the meter board. Take one picture to the left and one to the right with the meter board at the corresponding edges of the photographs. Stand 7 feet (2 m) away from the board. Tilt the camera slightly off horizontal to make the meter board parallel with the side of the photograph. Place the “1M” of the board in the upper corner of the view. The 7-foot distance, along with a 50mm lens on a 35mm camera, will place the bottom of the board in the lower corner of the picture (fig. 20). Set the camera to 3 meters (9 ft), which allows the vegetation to be in focus from bottom of the meter board to at least 7 feet (2 m) beyond the board. These are closeup views of figure 4, June 15. If pictures are mounted in this fashion, I overlap the meter boards so that only one is showing.

Analysis of Change

The meter board also is used as a constant size reference point for analyzing changes. The recommended system is grid analysis (discussed in part B). In a nutshell, a clear plastic form with site identification information is taped to the photo and topics of interest outlined. Then an analysis grid is adjusted to exactly match the size of the meter board in the outline and is printed on white paper. The outline form is taped to the grid, and grid intersects within the outlines are counted and recorded. Amount of change between photos can then be determined.

Topic Description

Describe the setting and topic to be photographed each time photos are taken. Figures 13 to 15 show mountain pine beetle effects on lodgepole pine. New conditions are recorded for each repeat photograph. Figure 11 illustrates a general photo and two closeup pictures of ground conditions. Plant species and their estimated canopy cover are recorded for the closeup pictures each time they are taken. The "Photo Points and Close Photos" form provides space for these notes.

- ◀ Figure 20—Orientation for closeup photos of a meter board in dense vegetation. In photograph (A) with 4 inches (1 dm) of stubble height, the meter board bottom can be visually estimated. In (B) and (C) it cannot. Exact reorientation of the photograph is essential: (1) the "1M" must be in the top corner of the view, (2) the bottom of the board must be in the lower corner, (3) the photograph must be taken from 7 feet (2 m) away with a 50mm lens on a 35mm camera, and (4) the camera must be tilted slightly off horizontal to make the board parallel with the side of the view frame. In photograph (B), just 3 months later, grass is over 16 inches (4 dm) tall effectively hiding the bottom of the meter board. Problems with tall vegetation and exact photograph reorientation are shown in (C). The "1M" was not placed in the top corner of the view frame. Instead it is about 8 inches (2 dm) below the corner meaning the bottom of the board is about 8 inches (2 dm) below the bottom of the picture, an unacceptable repeat photograph. Photo (C) also demonstrates a problem photographing plot frames because a frame would not be visible.

Shrub Profile Photo Monitoring

Change in shrub profile area can mean either shrub use or shrub growth. It may be documented through repeat photography with grid analysis and horizontal camera orientation. Permanent camera locations and photo points, marked by steel fenceposts or stakes, are required. Season of photography is a key factor in documenting change and causes of change in shrub profiles.

Concept

The concept of documenting change in shrub profile area is to photograph a shrub on two sides with the camera location moved for a 90-degree difference between views (Reynolds 1999). This photographs all profiles of a shrub. Camera locations and photo points must be marked with steel fenceposts or stakes to assure the same distance from camera to meter board for all future photographs. The same distance need not be used, however, for all camera locations. Adjust distance to suit the topic being photographed. Tall shrubs, where double meter boards are used (fig. 21), require a much greater distance than short shrubs (fig. 25, below).

Once photographs have been taken, use the photo grid analysis procedure (in part B) to document changes in shrub profile area and shape.

Guidelines

All basic photo monitoring requirements for relocating the monitoring area and for maintaining the same distance from camera to meter board must be met. Some guidelines follow.

The primary objective in monitoring change in shrub profile area or shape is to document usage (reduction in area, Reynolds 1999) or growth (increase in area). Thus, season of photography is of critical concern. If effect of animal browsing is the topic of interest, photography both before and after this use may be necessary. This requires selection of two seasons to photograph, such as just before livestock grazing and immediately after. If livestock graze at different seasons in the same pasture over a period of years (such as rest-rotation systems), three dates may

Figure 21—Use of a folding 2-meter board to document height and growth of tall shrubs. This board is hinged in the middle and held upright by a barrel bolt. When folded together (fig. 54, part B), it is a 1-meter board and unfolded it is 2 meters.

be required to document grazing effects over several years. Other dates, established by local knowledge, probably will be required for wild animals.

If growth in shrub profile area is the topic of interest, then photography after termination of growth would be desirable. Dryland shrubs usually have a definite termination of growth and are called determinate shrubs. Some riparian shrubs, such as many willows, continue to grow until environmental conditions, such as frost, cause growth to stop. These are indeterminate shrubs. Season to photograph must thus be based on the physiological development of the shrub species under study.

Procedures

1. Establish a monitoring objective at the same time as the area and species of shrub to evaluate are selected. Determine photography date(s).

2. Make a map to find the monitoring area (fig. 5) and a map of the transect layout (figs. 22 and 23). The transect layout must include direction and distance from the witness mark to the first shrub photo point and then its two camera locations, and from there the direction and distance to the next shrub photo point and its camera locations (fig. 23). All shrub photo points must be tied together for ease in future location. The transect layout need not, probably will not, be a straight line (fig. 23).
3. Placement of the meter board is critical because it will be used to document changes in shrub profile. There are three concerns: (1) Placing the meter board far enough to the side of the shrub to allow the shrub to grow in crown diameter (figs. 24 and 25). Consider a distance that is half the current shrub crown diameter (fig. 24). (2) Placing the bottom of the meter board far enough toward the camera to assure the lowest line of the grid will be **below** the bottom of the shrub if it grows. Consider placing the 2-decimeter line opposite the current bottom of the shrub (fig. 25). (3) Placing the board in one location and moving the camera for a 90-degree change in view (figs. 24 and 25).
4. Select a camera-to-photo-point distance that will permit the shrub to grow in both height and diameter. Consider a distance where the current shrub is about 50 percent of the camera view height and 70 percent of the camera view width (fig. 25, A and B).
5. Try to select a single shrub or several shrubs separated from other shrubs in the camera view. If shrubs increase in area of profile, their outer crown periphery may become difficult to separate from adjacent shrubs (fig. 25). Color photographs greatly aid in shrub profile delineation.
6. Aim the camera so that the meter board is at the extreme left or right of the view (fig. 25). The "Shrub Analysis Grid" (part B, app. A) shows the meter board at the sides (fig. 25). Next,

MAP

Figure 22—The filing system form "Sampling Site Description and Location" identifies the Pole Camp shrub profile monitoring system. On the first line of the form, circle the monitoring system used, in this case "Shrub Form." Information about the area is entered, and a map is drawn to locate the monitoring system. This shrub profile transect is one of several photo monitoring installations at Pole Camp; figure 6 diagrams five camera locations and four photo points. A note at the bottom of this map says that an attached page has details. This is shown in figure 23.

Figure 24—System for locating a meter board when photographing shrub profiles. Measure the shrub radius in two directions, at 90 degrees from each other to correspond to the direction of photographs (12 inches [30 cm] and 10 inches [25 cm]). Move out from the shrub the same distances (12 inches and 10 inches), and locate the meter board at the intersection of the distances. This will place the meter board far enough to the side and front of the shrub so that the shrub can grow and still be covered by a grid. These two views correspond to figure 25, 1A and 1B.

Note the relation between placement of the meter board bottom about 8 inches (2 dm) below the bottom of the shrub and orientation of the camera at the bottom of the meter board. The objective is to document change in shrub profile both upward and outward.

When tall shrubs require double meter boards, such as in figure 21, the boards may be placed in front and the “Analysis Grid-2-Meter” form (part B, app. A) used.

Figure 25—The filing system form “Shrub Photo Transect” (part B, app. A) shows Pole Camp willow transect 1 and both views of shrub number 1. Notes about the vegetation and item photographed are made opposite each photograph. Direction shown is from the **camera** location to the shrub—a reciprocal of the map direction. The form provides for two views each of 10 shrubs with views down the transect from each end. The top photograph (T = transect) is down the transect under which are photo points 1A and 1B. Species are *Salix geyeriana* Anderss., *Carex simulata* Mackenzie, *Poa pratensis* L., and *Potentilla flabellifolia* Hook. ex Torr. & Gray.

Equipment

The following equipment is required for shrub profile sampling:

1. Camera or cameras with both color and black-and-white film, or a digital camera.
2. Forms from part B, appendix A: for transect and shrub identification, "Shrub Photo Sampling" printed on medium blue paper, and data/photo mounting form "Shrub Photo Transect" printed on medium yellow paper.
3. Meter board (part B, app. B).
4. Clipboard with its support for holding the photo identification forms (part B, app. B).
5. Fenceposts and iron stakes sufficient for the number of shrubs desired: 1 fencepost and 2 iron stakes per shrub. Include a pounder.
6. Compass and 100-foot (30-m) tape.
7. Metal detector for locating transect stakes.

Technique

The technique for shrub profile monitoring combines a transect system with principles discussed in "Topic Photography," above, and in part B, "Photo Grid Analysis." A primary objective is to monitor **change** in shrub profile area and not to measure canopy cover of shrubs or shrub profile area per acre (hectare). Shrubs, therefore, are objectively selected for photography. The following technique emphasizes this objectivity.

1. Locate the area of consideration. Walk the area to select shrubs to be monitored. In many cases, shrub distribution does not lend itself to straight line transects, particularly in riparian areas with winding streams. Ask, "Why am I concerned with change in shrub profile area? Is it to appraise usage, assess vigor, or document change in profile area? Is the location of shrubs important, such as creating shade along streams? Each shrub is a topic and becomes the key mapping and photo orientation object.

2. Mark each shrub to be photographed with steel fenceposts or a combination of posts and stakes: a fencepost to mark the meter board and two more posts or stakes to mark camera locations that view the shrub at 90 degrees (two different sides). Whenever possible, select a single meter board position that will accommodate the two camera locations (figs. 24 and 25).
3. After marking all the desired shrubs, diagram the transect layout (fig. 23). Take a direction and measured distance from the witness marker to the meter board position for the first shrub. Diagram the two camera locations with direction and distance **from** the shrub. This aids repeat photography. Find the shrub fencepost or stake, take direction, and measure distance to the camera locations. Fenceposts are easy to find. Stakes require a metal detector, which is greatly facilitated by this location system. The distance and direction should locate a 0.5-meter diameter area in which to find the stake.

Then take direction and measured distance from the meter board for the first shrub to the second shrub, again documenting direction and distance to the camera locations. Continue to the end of the transect (fig. 23). Remember to indicate magnetic or true direction.

4. When ready to photograph, fill out the filing system form "Shrub Photo Sampling" for photograph identification as seen in the three parts of figure 25.
5. Take a general picture of the transect by setting the meter board at shrub number one as shown in figure 25T. Stand 20 to 30 feet (7 to 10 m) from the board and put the "Shrub Photo Sampling" form in view (fig. 25T). Stake the camera location and add the location to the sampling layout diagram.
6. For each shrub, place the "Shrub Photo Sampling" photograph identification form next to the meter board (fig. 25, 1A and 1B). The form has a shrub number and letter for camera

locations for 10 shrubs. Match the shrub number and letter on the form with the transect diagram and circle the number, in figure 25-1A, 1A is circled for camera location "A." To photograph the shrub, focus the camera on the meter board to assure greatest depth of field for the shrub. Then swing the camera either left or right to place the meter board at the side of the frame.

Move to the second camera location (1B), turn the meter board and the photo identification form to face the camera, cross out the last shrub number on the form and circle the current one. In figure 25-1B, 1A is crossed out and 1B is circled representing shrub 1, camera location "B."

Make notes of what is in each photo on the "Shrub Photo Transect" form printed on yellow paper (fig. 25) from part B, appendix A. Identify the shrub, list herbaceous vegetation, and note anything of interest such as browsing and by what.

7. Move to the next shrub and repeat the process until completed.
8. Mount the photographs, as shown in figure 25. The filing system form "Shrub Photo Transect" is designed for 3- by 4½-inch (7.5- by 11.2-cm) photos.
9. Conduct grid analysis of the pictures as discussed in part B (fig. 26).

Tree Cover Sampling

Forest stand density, represented by canopy cover, has direct influences on ground vegetation species through root competition and by casting shade. Trend in density and composition of ground vegetation is often as much influenced by this competition as by grazing or light disturbance. Any photo point placed in a forested setting should consider tree cover photography.

Figure 26—Grid outlines for shrub 1, views (1A) and (1B) on the Pole Camp shrub profile transect. Grids have been adjusted for size by the outlined meter board. Outlines are then taped to the grid. Count grid intersects and record on the filing system form "Photo Grid Summary" (fig. 49, part B).

Figure 27—System to photograph tree canopy cover. The photo point meter board will be crosswise of the view. Place the camera level board on top of the meter board and the camera on the level board. First, center the cross-view level by moving the meter board sideways. Then tilt the camera level board so that the down-the-view level is centered, move your head out of the camera view, and photograph.

Concept

Tree canopies are photographed perpendicular to the ground by using a camera leveling board to assure vertical orientation of the camera. Figure 27 illustrates a 35mm camera with 50mm lens in the correct position.

Whatever focal length is used to begin, the **same focal length** must be used for subsequent photos. There is no measured distance to a meter board or other size control used in the overhead view, therefore pictures **cannot** be adjusted to a common camera focal length to compare canopy cover.

Equipment

The following equipment is required for tree cover sampling:

1. Camera or cameras with both color and black-and-white film, or a digital camera.

2. A camera leveling board (part B, app. B).
3. Form from part B, appendix A, for data and photo mounting, "Photo Points with Overhead Views" (fig. 28)
4. Meter board (part B, app. B) on which to set the leveling board and camera and thus maintain a constant camera height.
5. A compass and 100-foot (30-m) tape.
6. Fenceposts or steel stakes with pounder.
7. Metal detector for locating stakes.

Technique

Position the meter board at the topic of interest following guidelines in "Topic Photography" (above). Hold the camera leveling board on top of the meter board, set the camera on the leveling board with the long axis crosswise to the scene (landscape orientation) and the viewfinder toward the camera location (fig. 27). The easy way to remember this is to view the photo point with the camera in landscape orientation (fig. 28, top view), then move to the meter board and rotate the camera to look up at the canopy (fig. 28, bottom view).

Move the meter board sideways to level the camera board across the view. Then level the camera board down the view, bend down to take your head out of the picture, and photograph (fig. 28, bottom view).

Important criteria—There is neither a size control (meter board) nor photo identification sheet in these pictures. Therefore three procedures **must** be followed:

1. The same focal length lens must be used for all subsequent photographs so that images can be compared.
2. The camera must be the same height aboveground. Use the meter board for consistent heights. Figures 31 and 32 in part B illustrate the effect of change in distance on size and location of objects.

Abstract

Hall, Frederick C. 2001. Photo point monitoring handbook: part B—concepts and analysis. Gen. Tech. Rep. PNW-GTR-526. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 86 p. 2 parts.

This handbook describes quick, effective methods for documenting change in vegetation and soil through repeat photography. It is published in two parts: concepts and office analysis in part B, and field procedures in part A. Topics monitored may be effects of logging, change in wildlife habitat, livestock grazing impacts, or stream channel reaction to land management. Land managers, foresters, ranchers, wildlife biologists, and land owners may find this monitoring system useful. In part B, (1) concepts and procedures required to use photographs for analyzing change in photographs are presented, (2) monitoring equipment specifications are given, and (3) forms for recording information and mounting photographs are provided.

Keywords: Monitoring, photography.

Preface

This handbook is an synopsis of repeat photography principles and photo point sampling from the publication *Ground Based Photographic Monitoring*, PNW-GTR-503, which is based on 45 years experience in repeat photography by the author. During those years, many nuances were discovered that bear discussion and emphasis so that new users can avoid the pitfalls I ran into. The terms *should*, *must*, *will*, and *do not* are used to help users avoid problems and are not meant as rules.

Introduction

Photographic documentation of soil and vegetation topics of interest is an essential first step in photo monitoring. But monitoring implies the need to determine change. This determination has two components: (1) the basics of photographic technique; and (2) a method to assess change—in this case, grid analysis, which may be done by hand or with a computer. Appendices provide forms for photo monitoring and analysis as well as equipment specifications.

Basics

Use of photographic equipment is fundamental to photographic monitoring. The equipment may be either film or digital cameras. The purpose of photo monitoring is to document change in a landscape or topic over time. Measuring change requires photographs of good to excellent resolution and color, both of which are influenced by camera and film.

Cameras

Consumer cameras currently are classed into two broad categories: point-and-shoot automatic and single lens reflex (SLR) for either film or digital use. Point-and-shoot cameras usually provide safe exposure in average light conditions to produce nice snapshots. The SLR cameras use a view-through-the-lens system enhancing photographic composition and have various adjustments for fine tuning exposure. They can take superior pictures. Digital cameras are similar, but their quality tends to center on the number of pixels. Pixels are dots of different colors that form an image. Point-and-shoot digital cameras range from 1.1 to 2.4 megapixels and better quality ones usually have 3.4 or more. If measurements on photographs are contemplated, one must use a camera of 2.4 megapixels or higher.

Film and digital camera characteristics—Both camera formats come in two configurations: (1) viewfinder and (2) view-through-the-lens, or SLR. Many digital cameras use SLR principles with a liquid crystal display (LCD). An LCD is a miniature (2.5- by 3.3-centimeter [about 1- by 1.3-in]) computer monitoring screen that displays the image as seen through the lens (Kodak 1999a). With through-the-lens systems, the image is viewed exactly as it will appear. There is no parallax correction and the image will look fuzzy when out of focus. The SLR cameras are more expensive. Viewfinders are parallel with the lens, and there is an outlined box in the viewer (parallax correction) to show what the image will cover when pictures are taken at close range. The image always will appear sharp.

Both film and digital cameras provide for a strobe flash system. Less expensive cameras often have built-in flash that fires straight ahead and is effective up to 9 feet (3 m) for low-light conditions and as fill-in light for up to 16 feet (5 m). More expensive cameras provide a hot shoe to which a more powerful and adjustable flash system can be attached. Additional flash systems add cost to the camera. Some cameras have both an internal flash and a hot shoe.

Zoom lenses have become popular, particularly with the “point-and-shoot” automatic cameras. They are common on many digital cameras. These lenses add flexibility to the camera, but they tend to be less sharp than a fixed lens. Zoom lenses may pose problems in photo monitoring because lenses need to be carefully set to reproduce the original image. This is difficult, if not impossible, with zoom lenses that might range, for example, from 35mm to 100mm focal length for a 35mm film camera and 9.2mm to 28mm for a digital camera. This allows for a threefold difference in photo coverage. See the section on camera format (below) for details.

The lens speed on film cameras is given in f-stops. The “f” indicates how large a hole is open to admit light into the camera. Small f-stops admit much light and large f-stops admit little. For example, under a given light condition, f-8 might require 1/60 second exposure, but f-5.6 would require 1/120 second because it admits twice the light, and f-3.5 would require 1/250 second because it admits four times the light. The f-stop also influences depth of field. The length of in-focus distance increases with increasing f-stops. When a 35mm camera is focused at 30 feet (9 m), f-8 is sharp from 15 feet (4.5 m) to infinity, f-5.6 from 20 to 60 feet (6 to 18 m), and f-3.5 from 25 to 40 feet (7.6 to 12 m). Digital camera speed usually is provided by the processing unit in the camera computer, and faster speed costs more.

Resolution, the sharpness of the image, in film cameras is a function of (1) lens quality, providing that the camera was properly focused; and (2) graininess of the film as determined by an ISO rating. Cost of film between ISO 100 and 400 is not much, but good lenses (low f-stop such as 1.8) are expensive. Film speed, the light required for an exposure, is characterized by an ISO rating. The graininess of an image also is a product of film speed—larger grain with faster film. Common ISO ratings are 100 for medium speed and relatively fine-grained film, ISO 200, which can be shot at twice the shutter speed and has medium graininess, and ISO 400, which can be shot at four times the shutter speed of ISO 100 but is rather coarse grained.

With digital cameras, resolution is determined by maximum dots per inch (dpi) of the camera. Each image is characterized by dpi across the width and a vertical dpi, such as 1200 by 900 dpi for a total of 1,080,000 dpi, which is referred to as 1.1 megapixels (a pixel is one dot). Digital camera equivalents for film ISO ratings are about 1640 by 1460 dpi for ISO 400 (2.4-megapixel camera), 1960 by 1640 dpi for ISO 200 (3.2-megapixel camera), and 2280 by 1800 dpi for ISO 100 (4.1-megapixel camera). To determine the camera rating, multiply the two pixel numbers: $1200 \times 900 = 1.1$ megapixels.

As of January 2001, most digital cameras started at about 1.1 megapixels, suitable for 4- by 6-inch (10- by 15-cm) snapshots, and went up to 4.4 megapixels appropriate for 14- by 17-inch (35- by 42-cm) pictures. A 2.4-megapixel camera or higher is required for grid analysis (film speed of ISO 400 or less). Resolution also is enhanced by good quality optical lenses. Most digital cameras offer a choice of three to five resolution levels. For example, a 1.1-megapixel camera might offer its best at 1200 X 900 dpi, midresolution at 900 X 700, and lowest at 600 X 400 dpi. Finer resolution results in fewer images on a digital memory card and slower processing. Quality also is influenced by the kind of compression, if any, used to store the image. Compression permits more images to be placed on a memory card.

Film and digital concepts—The digital camera could be considered a special purpose computer designed to take photographs (Kodak 1999b). This dramatically separates it from a film camera, which physically captures images on a role of film. The images cannot be altered on the film, but they may be altered in the printing process. Digital images are captured on an electronic storage or memory card, which must be processed to produce an image. A digital image can be altered by

the camera through different settings. Images are made up of dots called pixels, each composed of three colors: red, green, and blue; intensity of each color can be adjusted. Film and digital storage cards are discussed in the next section.

A camera using slide film exposes an image on film—**period**. Once the exposure is made, there is no recourse through correction. With black-and-white and color negative films there is some recourse through changing print exposure time, selection of paper, and dodging or burning items to be enhanced.

With digital cameras, the image is only one link in the chain to a photograph (Kodak 1999a). This chain is (1) the camera with its dpi, or pixel resolution, lens quality that captures the image, and the camera's ability to modify pixel characteristics; (2) the CPU (the computer) that processes the image with its ability to make major changes in the pixels and thus the image; (3) the monitor with its color projection of the image on the screen, which is used as a basis for changing the image characteristics; and (4) the output device, which either prints the image (printer) or projects it (projector). Resolution (dpi), color quality, and contrast are affected at the camera, CPU, and output device. Best image quality is attained by matching the camera resolution with that of the output device. They may **not** be the same.

Output (a picture) differs between film and digital cameras. Prints are similar because they are an image printed on paper. Prints from color film, black-and-white film, and digital images all share the same end result—a picture one can hold in their hand or mount on a monitoring form.

In contrast, slides made from film and digital images share few common traits. A film image is determined at exposure and can be projected with a slide projector in presentations. A digital image cannot. Generally, the digital image must first be downloaded from the camera and placed into the memory of a laptop computer. Then the laptop must be connected to a digital slide projector for presentation. Recently, cameras have been programmed for download directly to a projector; however, this projects only images in the camera. It does not provide for a presentation using title, data, and instructional images.

Camera focal length—Photo monitoring is greatly facilitated by using the **same** focal length lens for all repeat photos. Use of the same focal length is highly desirable but not essential (Rogers and others 1983). If the same focal length is used, subsequent pictures can be compared side by side. If different focal lengths are used, pictures must be adjusted in size to be compared, which will be discussed in “Camera Format and Distance to Photo Point,” below. Conversion from film to digital cameras usually will result in a change of focal length, because the digital camera must be adjusted to match the film camera lens. Digital camera adjustment often is not precise enough to exactly equal the film camera; for example, setting it at 13mm to copy a 50mm lens. Nothing can be done with slides taken at different focal lengths.

Recommendation—Specify the make and focal length of camera(s) to use in the monitoring.

Figure 29—A system for combining color and black-and-white photography. Both cameras are connected by strap aluminum 1/8 inch thick and 1 inch wide bent into a “U” with holes drilled for mounting screws to connect the cameras (see app. B for details). The cameras operate independently. Identical cameras simplify the photography because all control settings are adjusted in the same way, which helps in avoiding mistakes. Shown here are cameras with black-and-white film at 400 ISO and color film at 200 ISO.

Double camera system—My photography over the last 45 years used a pair of good quality 35mm SLR cameras and 50mm lenses (about \$500.00 each at 2001 prices), one for color and the other for black-and-white film. When both color and black-and-white photographs are to be taken, consider the camera system shown in figure 29. Both cameras are the same make and model to simplify adjustment for lighting and distance. Appendix B has details for constructing the apparatus.

Film and Digital Memory Cards

There are four ways to record images: (1) color slides, (2) color prints, (3) black-and-white prints, and (4) digital. Digital cameras are color and do not use film but, rather, memory cards.

Film—If film is used, both color and black and white are recommended because color film, slide or print, will fade with time and black and white will not. Once an exposure has been made on slide film, nothing can be done to enhance the image. Negative films, for either color or black-and-white prints, offer an opportunity to modify images in the print-making process. Different printing papers may be used, time of exposure can be adjusted, and overexposed or underexposed parts may be “dodged” or “burned” to enhance the image. Similar treatment, by computer manipulation, is available for digital images. But a word of caution, digital images can be so dramatically altered that they may not be admitted in a court of law.

Film comes in various degrees of graininess. This is roughly identified by film speed: the higher the speed, the grainier the film. For example, ISO 100 is relatively fine-grain film whereas ISO 400 is quite grainy. Digital camera equivalents are 4.1 megapixels compared to 2.4 megapixels. Determination of change between photos depends on the precision of measurement that can be made on a photo. Graininess limits precision.

Color rendition of vegetation is influenced by film chemistry. Tones can differ between brands from a single manufacturer, such as Kodak's Kodachrome compared to Ektachrome, and between manufacturers, such as Fuji and Kodak. Film developing may produce different tones from the same kind of film. Color prints from the same negative can differ depending on how the prints were made. Time of exposure and kind of paper are critical. Subtle changes in green as the season progresses might not be captured from one year to another or from one kind of film to another.

Processing of film will influence how well photos can be compared. Most film is sent to a commercial processor where either slides are produced or pictures at a standard size are printed, such as 3 by 5 or 4 by 6-inch (7.5 by 12.5 or 10 by 15 cm). Quality of processing differs. Do not cheapen your product by cutting costs and quality at the final step (Johnson 1991).

Digital memory cards—Digital cameras do not use film but, rather, electronic memory cards (Kodak 1999a). Unlike film, memory cards do not have to be developed; they are processed by computer. Any or all images can be erased and the card reused. The color quality, contrast, and depth can be manipulated. Selected images or all of them can be copied from a memory card to another media, which greatly facilitates their storage and retrieval.

Different makes of cameras use different memory cards. Memory cards come in several configurations: Compact Flash and Smart Media are about half the size of a credit card and about as thick. Some cameras use a 1.44-megabyte floppy (3.5-inch diameter) and others use a 140-megabyte Super Disc floppy.

Memory cards differ in their megabyte capacity. Smart Media offers 2 to 64 megabytes and Compact Flash 2 to 160 megabytes. Many digital cameras are sold with an 8-megabyte card, but larger capacities are usable. Megabyte capacity directly limits the number of images that can be stored. A general conversion from number of pixels in an image to number of images per storage card is a 1:1.2 ratio: a 1-megapixel photo requires about 1.2 megabytes of storage card capacity. For example, an image at 1200 X 900 pixels (1.1 megapixels) would require an entire 2-megabyte card, or 29 photos could be placed on a 32-megabyte card. The same 32-megabyte card would hold 51 photos at 900 X 700 pixels (0.63 megapixels) from a camera's lower pixel setting.

Digital memory cards can be reused. The deleted images, of course, are lost.

Processing memory cards is quite different from film. There are two alternatives: commercial or home processing. Commercial means the memory card is sent to a digital processing laboratory for prints similar to film. Home processing requires use of a CPU with a download system from the camera and a printer. For best image quality, the dpi of the camera and printer should be compatible. Image quality is sacrificed if the printer cannot process the dpi of the camera. And image quality may be sacrificed by color rendition of the printer.

Digital images may be stored in any of three ways: (1) in the memory card used with the camera, (2) by being transferred to a compact disk (CD) or zip disc and the memory card reused, or (3) by being transferred to a computer hard drive with essential information in its file and the memory card reused. If images are stored in a computer, assure that instructions for locating the folder or file are placed in the photo monitoring filing system. Disks should be placed in the monitoring file (see "Filing System" below).

Color prints from film and digital systems are similar in cost; however, slides made from digital memory cards tend to cost more. A negative must be made at about \$5.50 and from it the slide for another \$2.25, for a total of about \$7.75 each. And the need for two steps, from card to negative and from negative to slide, tends to reduce quality of the image.

Recommendation—Specify the brand, type of film, and ISO rating that will be used; for example Kodak Elite Chrome ISO 200 color slide film and TMAX ISO 400 black-and-white film.

Camera Format and Distance to Photo Point

Camera format is the combination of camera body image size and focal length of a lens. Format concepts apply to both film and digital cameras. Exact duplication of camera format is not of critical concern (Rogers and others 1983) when evaluating change in the subject photographed. Images may be enlarged or reduced to a constant area of coverage, printed, and compared.

Concept—With slide film, images taken with different camera formats will project differently on the screen. This is a major concern discussed by Magill (1989) in his analysis of change in campgrounds. He projected slides onto a screen with a grid and adjusted size of the image according to specified criteria prior to analysis.

Figure 30—This landscape was used to test effects of camera format (focal length) and distance from camera to photo point (meter board) on determining size and location of objects. Camera format is 35mm image with two focal lengths: 35mm wide angle and 50mm standard. Distances are 23 and 33 feet (7 and 10 m) to the “1M” meter board. Numbered items are outlined and compared: (1) bucket between camera and the “1M” meter board; (2) double meter boards 23 feet (7 m) behind other “1M” meter board; (3) tool box; (4) top of 2-meter board parallel with the “1M” meter board, (5) cart 49 feet (15 m) from the “1M” meter board, (6) lamp pole 164 feet (50 m) from the “1M” meter board. Two situations are evaluated: (A) change both distance and focal length such that the meter board is the same size in both pictures (figs. 31 and 32), and (B) vary the camera focal length at a given distance (figs. 33 and 34). The fencepost at center front marks the 7-meter distance, and the photo identification sheet lists the focal length and distance to identify the negative.

Some examples of common film camera formats that cover about the same area of a landscape are (1) 25- by 35-millimeter (1- by 1.5-in) image size (35mm camera) using a 50mm focal length lens, (2) 2- by 2-inch (50- by 50-mm) image size using a 70mm lens, or (3) a 4- by 5-inch (100- by 125-mm) image using a 128mm lens. All are equivalent to a digital camera at 13mm focal length.

The advent of good quality zoom lenses permits a great variety of camera formats, but zoom lenses have both desirable and undesirable features. A desirable feature is increased flexibility in choosing photographic formats without the need to change lenses. Undesirable features include higher f-stops and no constant focal length when rephotographing monitoring sequences.

Testing in a landscape—The effects of camera format and distance from camera to photo point are shown and discussed in figures 30 through 34. Change in emphasis on a topic through distance is depicted in figure 16 in part A.

Figure 30 is a testing landscape where six objects were positioned, photographed, and outlined to compare their size and location with change in distance and focal length. I used two camera formats with a 35mm camera body; a 35mm wide angle

Figure 31—Both focal length and distance to meter board are adjusted to make the meter board the same size in each photograph: 50mm at 33 feet (10 m) and 35mm at 23 feet (7 m). Each of the six items have been outlined on clear plastic overlays as follows: 50mm at 10 meters in a solid line and 35mm at 7 meters in a dotted line. Note differences in backgrounds even though meter boards are the same size. Figure 32 compares the object outlines.

Figure 32—Object outlines from figure 31 overlaid to evaluate the effects of camera focal length and distance from camera to meter board on size and location of objects. The overlays for 35mm at 7 meters and 50mm at 10 meters show both different sizes and locations of objects even though the meter boards are the same size. This is because geometric angles from camera to objects change as distance changes. If objects in photographs are to be measured for change, distance from camera to meter board must remain the same. This is further demonstrated in figures 33 and 34.

lens was compared to a 50mm normal lens as a standard for evaluation. They are equivalent to digital cameras of 9mm and 13mm. The focal lengths were used in conjunction with two distances from camera to meter board: 23 feet (7 m) compared to 33 feet (10 m). Figure 30 illustrates the 50mm lens on a 35mm camera.

Camera format and distance—Both camera format and distance to meter board were adjusted in figure 31 to photograph the meter board at a constant size. The 35mm lens at 23 feet (7 m), dotted outline, gave the same size meter board as 50mm at 33 feet (10 m), solid outline. But note the different backgrounds. Comparison of object outlines in figure 32 shows that all objects are different in both size and location except the meter board. They are different because geometric angles between the camera and objects changed as distance varied from 10 to 7 meters.

Next, focal lengths of 35mm and 50mm were used at a distance of 33 feet (10 m), illustrated in figures 33 and 34. Figure 33 appears to show very different scenes. They are different in what is included within each photo. But when the 35mm image (dotted outline) was enlarged to size the meter board to be equivalent to that taken

Figure 33—Effects of change in camera focal length of 50mm and 35mm at 10-meter distance from camera to the “1M” meter board. Objects in each photograph were outlined on clear plastic overlays and adjusted in size to the 50mm at 10 meter board as follows: the 50mm at 10 meter “1M” board was measured at 20 millimeters and the 35mm at 10 meter “1M” board at 14 millimeters; the percentage of enlargement was calculated as $20 \div 14 = 143$ percent. The 35mm at 10-meter outline was enlarged 143 percent. They are compared in figure 34.

Figure 34—Object outlines for 35mm and 50mm camera focal lengths taken at 10 meters from the “1M” meter board (from fig. 33). Overlaying the enlarged 35mm on the 50mm shows little difference in object size or location. Camera focal length may differ without affecting analysis of photographic items when images are adjusted to a common size meter board. Comparison with figures 31 and 32 clearly demonstrates that distance from camera to meter board must remain the same.

at 50mm (shown in figure 34; solid outline), each object is almost exactly the same size and location. This effect is what Rogers and others (1983) discuss. Figures 31 through 34 clearly indicate that distance from camera to meter board is critical, whereas focal length is not.

Weather

How does current weather compare to conditions of previous photographs (Magill 1989, Maxwell and Ward 1980)? A dense, heavy cloud layer will produce different colors and tones compared to a high, thin overcast, which in turn will be different from full sunlight with attendant deep shadows. Maxwell and Ward (1980) suggest overcast skies to reduce shadows and taking at least three different exposures to achieve comparable color between photos.

Photo Grid Analysis

To quantify changes in vegetation, soil, fuel loading, streambanks, or other photographic topics, outline the selected topic on a clear plastic sheet. Then place a grid under the sheet. Count grid intersects falling on and within the outline, and record. Compare these to counts from previous photographs of the same topic to estimate change. Each plastic sheet with its outlines and associated counts is a set of data and must be identified clearly and then archived.

Figure 35—A 1981 view of the Pole Camp wet meadow photo point, which will be used to illustrate grid analysis. This photograph will be compared to one from 1996. The first step is to attach a clear plastic outline form (shown in fig. 36). Fill in the required site information and outline the shrubs (fig. 37).

An alternative method is digital analysis by computer. The computer cannot differentiate between pixels on the topic and those behind the topic that are of similar color (fig. 35). A plain colored backdrop is needed behind the topic (Reynolds 1999).

Concept

Grid analysis is based on standardized geometric relations between photograph, camera, and meter board. Having the same focal length lens, distance from lens to meter board, height of camera above the ground, and photograph size simplify the analysis. A set distance between camera and meter board for the initial and all subsequent photographs of a specific topic is a **must**. Different distances may be used for different topics (fig. 16 in part A). A standard camera height is desirable, but it is not essential unless the grid is used to track change in position of items over time, a tenuous procedure. Use of the same camera format, such as 50mm lens on a 35mm camera body is recommended but not required. Grids are designed to encompass a view limited to 13 to 15 degrees both horizontally and vertically. This limit is emphasized by heavy lines surrounding the grid see (fig. 39, below).

Obtain a color 8- by 12-inch (20- by 30-cm) photograph of the topic (see fig. 35), for easy viewing. Attach to the photograph a clear plastic sheet with the form “Grid Intersect Analysis” printed on it, for information on date, site location, and topic (fig. 36). This is used to outline objects. Then measure the meter board to calibrate the grid (distance between grid points and area of grid cells). Use a copy machine to precisely adjust grid cells to match the dimensions of the meter board: each grid cell

	Date		GRID INTERSECT ANALYSIS	Area	
	Observer			Unit	
	Cluster/Camera			Transect/Photo	

Figure 36—Form used to identify photographic outlines. Print the form on clear plastic overhead projection sheets. This form has been reduced to 85 percent of the size in appendix A. The full sized form is suitable for 8- by 12-inch color photographs. Use of the clear plastic overlay is illustrated in figure 37.

Figure 37—Photographs to be evaluated by grid analysis: (A) 1981 (from fig. 35), and (B) 15 years later in 1996. Clear plastic overlays (fig. 36) have been taped to each photo. Each overlay is a data sheet and therefore must have all information entered to identify the outlines. Date is the **photograph** date, not when the outline was drawn. First the meter board is outlined on its left side and top. Then each visible decimeter line on the meter board is marked and the decimeter number written on the overlay. Finally, each shrub is carefully outlined and given either a letter or number identification. The next step is size adjustment of the analysis grid (figs. 38 and 39).

Figure 38—Measure meter boards for size adjustment of analysis grids: (A) 1981 and (B) 1996. Measure from the top down to the lowest visible decimeter mark to the nearest 0.5 millimeter, in these photos the 2-decimeter mark. Both measurements are 22.5 millimeters, which indicates that both are the same distance from camera to board and there was consistent enlargement of the photos. The analysis grid (fig. 39) will have to be reduced in size to exactly match the size of the meter boards in these outlines. An exact match is required for consistency in measurement between photographs.

should span 4 inch (1 dm) on the meter board. Print the adjusted grid on white paper. Outline the meter board and topics of interest in the photo on the clear plastic (fig. 37). For precise grid calibration, the meter board height should be at least 25 percent of the photograph height, preferably 35 to 50 percent. Each individual picture must be measured for grid adjustment. Tape the outline form onto the grid, carefully match the outline meter board with that on the grid, and count grid intersects that fall on and within each outlined topic.

Setting the Stage

Photography suitable for grid analysis includes the following:

1. Camera location and photo point (meter board) must be permanently marked so that exact relocation is possible. Stamped metal fenceposts driven 2 feet (0.6 m) into the ground work well.
2. Choose a distance from 16 to 65 feet (5 to 20 m), appropriate to the topic, for each site. Place a size control board (a 1-meter board or a double, 2-meter board; see figs. 21 and 35 in part A) such that the visible part of the board occupies at least 25 percent of the picture height. Then the meter board can be used to orient the photograph and adjust size of an analysis grid.

With a 50mm lens on a 35mm camera, a single meter board set 33 feet (10 m) from the photo point would span 25 percent of the photo height (figs. 31 and 33); at 23 feet (7 m), 36 percent. A double meter board, 7 feet (2 m) tall (app. B), spans 25 percent of photo height at 66 feet (20 m).

When grid analysis is planned, clip vegetation away from the front of the meter board to expose the bottom decimeter line. This will provide for maximum precision in grid adjustment.

3. When photographing, aim the camera view at the meter board. Place the ring in the viewfinder on the "1M" and focus (fig. 18 in part A). This provides for (1) reorientation of all subsequent photographs, (2) a sharp image at the topic marked by the meter board, and (3) an optimum depth of field.

Materials

Materials and equipment required for grid analysis are as follows:

1. Photographs of the setting. Print all photographs to be compared at the same size, preferably about 8 by 12 inches (20 x 30 cm), and in color for best differentiation of items to analyze. Figure 35, for example, is the wet meadow photo point at Pole Camp as taken in 1981. It will be compared to a photo taken in 1996 to appraise change in shrub profile area (fig. 37).
2. Clear plastic sheets used for overhead projection, such as 3M or Labelon Overhead Transparency Film. Film is designed specifically for various copy machines, such as inkjet, plain paper, or laser. Imprint these sheets with site information by using the form in figure 36 ("Grid Intersect Analysis") from appendix A.
3. A grid master form, which is shown in figure 39 (form is in app. A). Adjust the grid in size to precisely fit each picture and the outlined meter board as shown in figure 39. Instructions for grid size adjustment are given below.
4. Photo Grid Summary form (fig. 41 and app. A).
5. Permanent markers, such as Sanfords Sharpie Ultra Fine Point Permanent Marker, for drawing on clear plastic. Use different colors to aid in differentiating items when their outlines overlap, figures 38 and 40. Black, red, and blue work well together.

Figure 39.—The master analysis grid is in appendix A. Measure from the top of the meter board to the 2-decimeter mark used in the outlines. This measurement is 37.5 millimeters. Divide 22.5 millimeters from the outlines in figure 38 by 37.5 for a reduction to 60 percent of the grid. Print the grid on white paper at 60 percent of its original size. The outline is laid over the reduced grid to check alignment of the meter board marks. Minor adjustments in grid size are made so that marks of the overlay and grid meter boards match exactly (fig. 40).

Figure 40—Outline overlays are placed on analysis grids for (A) 1981 and (B) 1996. The next step is to count grid intersects on and within each outline. When an outline crosses a grid intersect, such as between shrubs 17 and 19, AA-18 in photo (B), count the intersect for the shrub in front (number 17). Also count intersects along the grid edge, such as the five intersects in shrub 25 on line YY, photo (B).

6. Good quality hand lens to identify the periphery of items being outlined, in this case shrub profiles.
7. A copy machine that will produce clear plastic overhead projection copies and can adjust the size of the master grid to fit the photographs. Many copy machines can reduce to 50 or enlarge to 200 percent. Tape one grid, adjusted for size and printed on white paper, under each outline for analysis (fig. 40). Precisely align the outline meter board with the grid meter board.

Grid Adjustment

Outline interpretation requires use of a grid whereby each grid intersection on and inside an outline is counted and recorded. The grid must be adjusted in size based on the meter board outlined on each overlay.

1. Measure height of the meter board as it appears on the overlay to the nearest 0.5 millimeter. If the bottom line on the board is not visible, measure to the lowest visible decimeter mark. In figure 38 it is 2 decimeters, and measures 22.5 millimeters from top to 2 decimeters. Similar measurements between the 1981 and 1996 photographs indicate that distance from camera to meter board was the same and that both pictures were enlarged identically.
2. Next, measure height of the meter board on the grid. In figure 39 it is 37.5 millimeters from top to the 2-decimeter grid line (second from the bottom).
3. Determine the percentage of change required for the master grid: $22.5 \div 37.5 = 60$ percent. On a copy machine, reduce the grid to 60 percent and print on plain paper. Overlay the outline on the grid to determine any additional size adjustment (fig. 40). This usually requires two or three trials.
4. Place the clear plastic overlay with its outlines on the grid and ensure that grid divisions exactly match those on the overlay meter board. Orient the overlay on the grid by using the left side of the meter board outlines (fig. 40). When both overlay and grid meter board marks match exactly, tape the overlay to the grid.

Note the borders on the grid (fig. 39). These mark the maximum 12- to 15-percent angle useful for grid analysis.

Analysis of Photographs

Select a topic—For this example, change in willow profile area is the topic, thus, no other item—grasses, sedges, forests, or water—is outlined. Decide if individual shrubs will be evaluated or if all shrubs will be lumped together. In this case, individual shrubs will be evaluated. Proceed as follows.

1. Fill out all information on the clear plastic overlay ("Grid Intersect Analysis," app. A). It becomes the permanent data record and must be identified (fig. 36). Date is the **photograph** date, not the date of the outline.
2. Attach the plastic overlay to the photo at one edge, such as the top, so that it can be lifted for close inspection of the photograph and then replaced exactly (fig. 37).
3. With use of a straight edge, mark the left side of the meter board and its top on the overlay of each photo (fig. 37). Next, mark each decimeter division on the meter board and identify even-numbered decimeter marks by their number, such as 2, 4, 6, and 8 (figs. 38 and 40).
4. Select the topic; for example, shrub profile area. Start in front and work from left to right. Outline each element of the topic (shrub in this case) and label it with a letter or number (fig. 37). Labeling ensures that grid intersects on and inside an outline are not repeated or missed when recording data.

If identifying change in specific shrubs is desirable, each shrub identified in the initial photo will have to be identified in all subsequent photos, and the letter or number used initially will have to remain exclusive to the shrub or to the location where the shrub used to be. Any new shrubs will require their own exclusive new identification, such as shrub 1 in figure 37B.

5. When outlining, pay particular attention to the periphery of the shrub by following as carefully as possible the foliage outline. Do not make a general line around the outside of the shrub. Mark directly **on** the foliage, not outside of it. Check outlines by lifting the overlay to check the foliage and inspect with the hand lens.
6. Work back into the photograph. Overlapping shrubs are identified by the letter inside the front shrub outline (fig. 37). Overlapping outlines may be enhanced by using different colored marking pens. Intersects often will occur under an outline; count them for the shrub in **front** only (do not count the intersect twice).

Do not count intersects on outlines outside the grid.

7. On the filing system form "Photo Grid Summary" (fig. 41), fill in the required information and enter the year of the photograph in the "Date" column. This is the date on the plastic outline. List shrubs by letter or number in the "Item #" column. The form provides space for recording intersects for three photographs. Note that items, shrubs in this case, are not required to have the same identification. Here, shrubs from 1981 are letters and those from 1997 are numbers, because exact relocation of shrubs was not possible.
8. Starting in front and working from left to right, count the number of grid intersects on and within each outline. An intersect is where a horizontal and vertical grid line meet (intersect). Many times, the outline will separate two shrubs. When the outline covers an intersect, count it for the shrub in front. Do **not** count the intersect twice. See figure 40A: intersect BB-18 is on shrub "R" outline with shrub "Q" behind it. Record the intersect only for shrub "R." This is why outlining **on** rather than outside of shrub foliage is important. Do not try to count intersects of the shrub behind when they cannot be seen; for example, in figure 40A, intersects of shrub "Q" behind shrub "R." Count intersects on the edge of the grid but not beyond even though the shrub or outline might extend beyond the grid. The grid, not the photo coverage, defines the area of analysis.
9. Record the intersects for each shrub beside its letter or number (fig. 41). Recording by shrub letter or number is designed to simplify record keeping. One may stop or be disturbed at any time and still know what shrubs they have recorded and where to begin again. When finished, sum all the intersects.

Important note—Each picture is produced by enlargement of a negative. Seldom are two enlargements made at exactly the same scale even though the negatives might be precisely sized. Therefore, grids must be sized **independently** for each photograph (fig. 37).

Table 1—Effect of camera-to-meter-board distance on grid coverage at distances of 10, 20, 30, and 60 meters (33, 66, 98, and 198 ft) from the camera

Distance from camera to meter board	Ratio	Angle	Grid size at distance from camera of:			
			10 m	20 m	30 m	60 m
<i>Meters</i>		<i>Percent</i>	<i>Decimeters</i>			
5	1:50	2.0	2.0	4.0	6.0	12.0
7	1:70	1.4	1.4	2.8	4.2	8.4
10	1:100	1.0	1.0	2.0	3.0	6.0

height. Grids 2.2 percent larger in height are also 2.2 percent wider, which results in a 4.4-percent increase in outlined area. Thus the number of intersects on and within an outline can change by 4.4 percent.

A meter board occupying 33 percent of photo height would measure 1.2 inches (30 mm) in figure 38. A 0.02-inch (0.5-mm) difference here is only 1.7 percent change in grid size. The 1.7 and 2.2 percent represent measurement-precision errors.

Distance from camera to meter board also affects precision of measurement on items beyond the meter board. Table 1 illustrates the effects of three distances between camera and meter board and how they affect grid precision at various distances beyond the meter board. Because grids are adjusted to size at the meter board location, each grid is 4- by 4-inch (1 by 1 dm) in size at that location but changes as distances increase.

A grid adjusted to a meter board 16 feet (5 m) from the camera measures 8 inch (2 dm) between grid lines at 33 feet (10 m) from the camera. This is two times greater than a grid adjusted at 33 feet (10 m) from the camera. At 98 feet (30 m) from the camera, a grid adjusted to a board 16 feet (5 m) from the camera will cover an area 24 by 24 inches (6 by 6 dm). When adjusted to a meter board set 33 feet (10 m) from the camera, it will cover an area only 12 by 12 inches (3 by 3 dm)—one-half the dimensions and one-quarter of the area—a significant improvement in precision. Monitoring objectives help determine the optimum distance from camera to meter board when grid size adjustment and outline precision are being balanced.

Observer variability—“Perfect” outlines are influenced by three kinds of differences among observers.

1. Size adjustment of grids is influenced by observer skill. With a meter board at 25 percent of photo height, 0.02-inch (0.5-mm) measurement difference of the meter board can mean as much as 2.2 percent difference in grid dimensions and 4.4 percent difference in area. Meter boards closer to 33 percent of photo height and larger photographs help to reduce this error. I recommend 8- by 12-inch (20- by 30-cm) color photographs. A meter board at 33 percent of an 8- by 10-inch photo height would measure about 2.6 inches (66 mm). A 0.02-inch (0.5-mm) measurement difference would be only a 0.8-percent error.

Figure 43—Summary of seven observers determining grid intersects on 18 shrubs in the same photograph. Variation among observers is characterized by the 5-percent confidence interval (5%CI) and expressed by dividing the 5%CI by the mean intersects by shrub and multiplying by 100 (CI%Mean). The mean and CI% Mean are graphed by shrub below the summary data.

2. The grid must be oriented exactly along the left side of the meter board as viewed (that is, the observer's left side) and precisely at the top and bottom or lowest clear decimeter mark. Orienting precision is subject to observer skill.
3. Interpretation of what constitutes the periphery of a shrub profile is subject to observer variability. One must make choices about where to place an outline and how precise it will be, particularly on overlapping shrubs. Note that an intersect is counted if the outline crosses it. The desirability, good or bad, of the topic being outlined tends to influence a person's willingness to include or exclude marginal parts. Outlining on clear plastic without grid lines tends to reduce observer bias.

A test was made in January 1998 of observer variability in outlining the shrub profile area shown in figures 35 and 37A. Results of the seven observers are given in figure 43. Color prints, 6 by 9 inches (15 by 22 cm) with properly sized grids, were provided. Observers placed the grids, outlined shrubs, and summarized intersects

Outline Analysis - 2 photos, 99/3

Photo	FH1	FH2	EC	DR	DF	MN	SE	CQ	Mean	Std.Dev.	Cof.Var.	Max.	Min.	Range	% Range	5%CI	CI%mean
1975	376	364	394	473	386	330	359	393	384.38	41.59305	10.82096	394	330	64	0.1665041	28.8219	7.49839184

Figure 44—Outline analysis test for variation among eight observers in estimating shrub profile intersects. Photographs from 1975 (series 1) and 1995 (series 2) at the Pole Camp wet meadow photo point were compared. The 5%CI for 1995, 11.6 percent of the mean, is used to determine a significant change in shrub profile. FH1 and FH2 were observations by the same observer made 2 months apart to illustrate single-observer variability.

within each outline. Variation among observers was measured by the 5-percent confidence interval (CI). The CI also was calculated as a percentage of the mean: CI divided by the mean times 100 equals the CI% for each shrub, total of all shrub intersects, and an average CI. Low CI%, such as 5 percent (shrub H), is interpreted as low observer variability and that a change of more than 5 percent in intersects probably is a significant difference. High CI%, such as 25 percent (shrub B), means high observer variability and greater than 25 percent change is required.

The percentages for confidence intervals ranged from 4.2 percent (shrub L) to 54.4 percent (shrub D, fig. 43). The average CI% among the observers was 15.4 percent, which suggests that, to be significant, a change of more than 15 percent in intersects is required owing to observer variability. However, the CI% for total intersects of all shrubs combined was only 5.7 percent, indicating good concurrence between observers for the entire scene, a relation tested in 1999 and reported below.

The number of intersects in an outline seems to influence the CI%. Graphs at the bottom of figure 43 show higher CI% with lower intersects per shrub.

Differences in shrub profile area are rather clear in figures 41 and 42. Profile area in 1996 was 65 percent of that in 1981. Change in shrub profile is illustrated in figure 42. However, the reader may wish to test this for observer variability. Count the shrub profile intersects in figure 40 and compare to the data in figure 41.

Because CI% was rather high for individual shrubs, another observer variability test was conducted in winter 1999. Eight observers were provided with two photographs, one from 1975 and another from 1995, and asked to count total intersects of shrub profile. The CI% for 1975 was 7.5 percent and that for 1995 was 11.6 percent (fig. 44). The 1995 photo was more difficult to interpret.

The graphs in figure 44 illustrates the mean, 5-percent confidence interval, and observer variability by year. Using the largest CI%, 11.6 percent, the averages are significantly different at the 1-percent level of probability. Considering a maximum of 12-percent observer variability here and 15 percent for total individual shrubs, a value greater than 12 percent of the average intersects is proposed as being significant at the 5-percent level of confidence for observer variability. For example, a mean of 384 intersects must change by more than 46 to say that the change was real and not due to observer variability at the 5-percent level of confidence ($384 \times 0.12 = 46.1$). This may be expressed as 384 ± 46 and thus intersects greater than 430 or less than 338 may be considered a real change.

Studies, such as at Pole Camp where photographs are taken every year, are amenable to regression analysis of grid intersects. If the outlines are done by the same person, observer variability is reduced. Figure 45 illustrates regression on shrub profile intersects at Pole Camp from 1975 to 1997. Regression for the entire data set showed a decline at -0.63. However, when data were selected for the time when beavers were in the area, 1983 to 1994, the regression was at -0.90, highly significant. Trend lines such as these seem very useful.

Figure 45—Regression of outline intersects from 1975 through 1997 for shrub profile changes at the Pole Camp wet meadow photo point. One observer made all 25 grid measurements. Intersects are totals from inside the grid area. Circles are the yearly total shrub intersects. The line is a smoothing spine regression. A note at the bottom of the graph indicates years when beavers were present.

Analyzing Location

Documenting change in position of items on a photograph requires precise photography. Three kinds of precision are required: (1) distance between camera location and meter board must be the same for all repeat photos, (2) height of camera above the ground and placement over the camera location stake must be the same for all repeat photos, and (3) sizing and orientation of the grid must be precise.

These variables do not consider observer interpretation. They do suggest that attempts to use photographs for monitoring change in position of objects is questionable if they are distant from the meter board. Table 1 illustrates effects of distance on grid precision. If documentation of position change is desired, place the meter board near the topic of interest, such as a streambank, and measure on the ground from the meter board to the object of interest.

Shrub Profile Grid Analysis

A review of photo grid analysis is required for this evaluation. Only highlights specific to shrub grid interpretation are presented here.

Photograph the shrubs from two directions as illustrated in part A, "Shrub Profile Photo Monitoring."

Print the photographs to be analyzed at 8- by 12-inches (20 by 30 cm) and in color for good resolution.

Figure 46—Grid analysis of shrub 1 on the Pole Camp shrub profile transect (see map, fig. 23, part A). This view is "1A" of the two photos of shrub 1 (1A and 1B, figs. 23 and 25). Both photos of shrub 1 are shown in figure 25, part A. The "Grid Intersect Analysis" outline form has been placed on the photo, information filled in, and the meter board marked. Outline as carefully as possible the shrub profiles. Do the same for the other photo of shrub number 1 (figs. 25, 1B, part A, and 47).

From appendix A, select the "Grid Intersect Analysis" form and duplicate on clear plastic. Fill out all information at the bottom of the form. "Date" is date of the **photograph**, not when the outline was made. The completed outline will become a basic data file and must be identified. Tape the outline form to the photograph along one edge such that the outline may be lifted for close inspection of the photo and then replaced exactly.

Outline the shrub or group of shrubs in the photo. Two shrubs are shown in figures 46 and 47. They have been separated for illustration purposes. Do not try to guess the outline of a shrub hidden behind another. Outline only what can be seen. Be as precise as possible. In figures 46 and 47, large willow branches have been marked on the overlay. The branches are clearly shown in figure 25 in part A.

Figure 47—Outline of the second photo of shrub 1 (1B, fig. 25, part A), on the Pole Camp shrub profile transect. When two shrubs are present, separate their outlines as shown. Information at the bottom of the clear plastic overlay must be filled in for each photo. Remember to outline and mark the meter board. Outline **on** the foliage, not around it, to increase precision.

Next, adjust the shrub analysis grid, the one with meter boards at each side (app. A), to exactly match the outline meter boards as discussed in "Photo Grid Analysis," above. Tape the outline form to the adjusted grid (fig. 48).

Count intersects within each outline including those falling under an outline (fig. 48), and enter on the filing system form "Photo Grid Summary" (fig. 49). Refer to the section "Analysis of Change, Observer Variability," above, for a discussion of what constitutes a significant change in shrub profile area.

The reader may wish to test observer variability. Count grid intersects in figure 48 and compare to the results shown in figure 49. Expect a difference of three to six grid intersects.

Text continues on page 80.

Figure 48—Grid outlines for shrub 1, photos (1A) and (1B) (figs. 46 and 47), on the Pole Camp shrub profile transect. Grids have been adjusted for size by the outlined meter board. Outlines are then taped to the grid. Count grid intersects and record on the filing system form "Photo Grid Summary" (fig. 49).

Figure 50—File folder contents for the Crooked River National Grassland trend cluster C3. Several sizes of expanding folders may be used: two-fold shown here, four-fold, or eight-fold to fit the file size. Each folder is labeled and the last date of sampling is attached to the upper right corner (arrow). All items pertaining to the sample location are included in the file: (A) general area map (fig. 5); (B) the form “Sampling Site Description and Location” for a plot layout map (fig. 6); (C) a form for attaching photographs and recording data shown here as the “Photo Trend Sample - Nested Frequency,” similar to figure 11; (D) data summary forms shown here as “Nested Frequency Transect Data” and “Nested Frequency Cluster Summary”; (E) trend interpretation using “Range Trend Rereadings”; and (F) clear plastic holders for slides. Not shown are black-and-white negatives in their envelopes identified by date, cluster, and transect.

Filing System

Photo monitoring requires a way to file maps, data, slides, prints, negatives, or digital memory cards. My system places each study in an expandable file containing everything (fig. 50): local map to find the study site (fig. 5, part A), the “Photographic Site Description and Location” with map of the photo monitoring layout (fig. 6, part A), photo mounting forms for color or black-and-white prints (figs. 2 and 11, part A), analysis grids if used, and clear plastic slide holders. Negatives are filed in their envelopes from processing. Two prints are made of each negative, one for mounting and one to be kept in the envelope for future use. Digital images may be filed as memory cards or as compact disks (CDs), which are recommended. The disk

should have an index card where identification of each image is stored. If images are stored on a computer (not recommended), identify the location and name of the computer, and the file where stored.

The expandable files are in a file cabinet dedicated to sampling and organized first by geographic location and then by date for next photography. Filing of studies by geography greatly facilitates travel planning. Noting the next photography date on each file helps in seasonal planning (fig. 50).

Appendix A: Forms

This appendix contains forms for photo point monitoring. They may be copied onto three colors of paper or clear plastic for overhead projection, depending on their use.

Paper Color

Office forms are printed on standard white paper.

Field forms should be printed on either of two paper colors: blue for forms placed in photographs to identify each photo or yellow for field forms to ease eye strain. Outline forms for grid analysis are printed on clear plastic. Grids and summary forms are printed on white paper. Paper color suitable for each form is shown in **bold**.

Blue paper is Hammermill Brite Hue Blue or Georgia Pacific Papers Hots Blue to be used in photographs to identify the slide or negative. This shade of blue has proven to be least sensitive to changes in sunlight, from full sun to shade, and has the least tendency to “bleach out” in full sun.

Yellow paper is Champion Goldenrod or Hammermill Copy Plus GOLDENROD to be used for field forms. It has proven to be least annoying to eyes under direct sunlight when recording data, maps, diagrams, and other descriptions.

Clear plastic sheets for printing outline overlays are 3M or Labelon Overhead Transparency Film. These films are specifically designed for different printers such as laser, inkjet, or plain paper.

White paper is used for summary forms and for grids adjusted to the size of the outline overlays.

Forms and References

Forms are listed below by page number, and examples of their use are shown by figure number (figures are from both part A and part B). Several forms consist of two or three pages. The first page lists all pertinent items and the photo number. A second page leaves the photo number blank to be filled in as required. For example, "Camera Location and Photo Points" lists photo "A" and "B" on the first page and has a blank for photo points on the second page. Print enough of the second pages to mount pictures of the photo points established. Similar multipage forms are "Photo Points and Close Photos," "Photo Points with Overhead Views," and "Shrub Photo Transect."

Appendix B: Equipment

Introduction

This appendix illustrates equipment required for photo point monitoring. Six items are discussed: meter boards, photograph identification sheet holder, camera leveling system for overhead photography, bracket for using two cameras (one with color and the other with black-and-white film), orange tags for identifying monitoring sites, and flimsy fenceposts.

Meter Boards

Meter boards are used to mark photo points. They help in taking consistent repeat photographs by orienting the camera on the "1M" of the board. Sharp exposure at the meter board is assured by focusing the camera on the "1M." The meter boards also provide a size control in photographs that can be used to adjust analysis grids when measuring attributes in a photo. This section describes how to construct meter boards.

1-meter board—

Materials—Prices given are in dollars as of 2001.

	Cost
	<i>Dollars</i>
1 piece ½-inch, 4-ply plywood, finished on one side, exterior, 1 foot by 4 feet @ \$20 per sheet	3
3/16-inch-diameter steel rod, 36 inches long	1
Numbers:	
5¼ inches tall, on a reflector, adhesive, packet of 10 (need 2, 4, 6, 8)	4
(Alternative is 4-inch nail-on numbers [5 @ \$2 each])	(20)
Line or pocket level 4 to 5 inches long	4
16-ounce can of yellow spray paint, exterior	4
Screws:	1
2 line level screws #4 ⅝ inch	
9 spike plate screws #6 ¾ inch	
1 role black electricians tape	4
Total	21

Construction—Meter boards are constructed from ½-inch 4-ply plywood, at least exterior quality and preferably marine quality (waterproof glue). Waterproof glue is desirable when sampling in riparian areas is expected because the meter board often will be placed in water. Dimensions and layout are shown in figure 51. Cut out according to specifications (fig. 51).

Prime the front of the board before painting. Then apply two coats of dull textured yellow to reduce reflection from the sun. Yellow is used for visibility. If dull yellow is not available, do not sand or smooth the front of the board. Roughness tends to diffuse sun reflection because it adds roughness to the paint. Most of a 12-ounce pressure can will be required for two coats.

Figure 51—Construction details of a 1-meter-tall meter board. The same measurements are used for the 1-meter-tall folding board. A 2-meter folding board, hinged at 1 meter, has a 2-centimeter difference in board heights. See figure 54 and text for details.

Figure 52—A line level is used to orient the board vertically. Obtain a 4- to 5-inch-long (10- to 12-cm) line level and drill a hole in each end for a screw. Attach one end of the line level to the back of the meter board $\frac{1}{2}$ inch (1 cm) from the top. Then orient the board vertically by using a carpenters level along one side. Hold the board in position, adjust the line level to horizontal, and carefully screw in the other end.

Numerals—The numerals 2, 4, 6, and 8 should be black and at least 4 inches tall. My preference is 5 inches tall for good readability when slides are projected. All illustrations in this publication show 5-inch numbers. There are many sources of these, including paste-on numbers, numbers on a card that must be cut out, and nail-on numbers. I use $5\frac{1}{4}$ -inch-tall numbers on a reflective card with adhesive on the back. Each number must be cut out and applied to the painted surface. The “M” for “1M” is made from electrician’s tape or it may be painted on.

Black marks at each decimeter and bands at top and bottom may be applied in either of two ways: painted at 0.78 inch (2 cm) wide or by use of black electricians tape, which is $\frac{3}{4}$ of an inch wide (1.8 cm). The top, bottom, and decimeter marks are used to adjust grid size before grid analysis of items in the photographs. The marks on the meter board, therefore, must be positioned exactly (fig. 51).

Line level—A line level is attached to the back of the board at the top (fig. 52). This allows the board to be oriented vertically, which not only is essential for grid analysis but also makes pictures look good.

Figure 53—Spikes in the bottom of the board are pushed into the ground to hold the board upright. Use 3/16-inch-diameter steel rod about 30 inches (75 cm) long. Bend it into a “U” shape as shown by the dotted line. It is placed under a plywood plate and held in place by nine screws. Leave about 6 inches (1.5 dm) of rod below the board. (A) Insert screws on each side of the rod at the bottom; (B) insert three at the top to prevent upward and downward movement of the rod; and (C) place one at each side at top to prevent sideways movement. Drill out doweling to fit over the spikes for safety.

Steel spikes—Steel spikes are attached to the bottom of the board (fig. 53) to hold it in the ground. Steel rod 3/16-inch in diameter works well because it is strong enough to hold the board upright and small enough in diameter to be pushed down into rocky soil. Spikes should extend 6 inches (15 cm) below the bottom of the board (fig. 53). Rods come in 36-inch lengths. About 30 inches is required. Bend the rod into a “U” shape to match the dotted outline in figure 53. Doweling drilled out to fit the rod is placed over the spikes for safety.

For convenience, a carrying handle may be attached to the edge of the board around the 5-decimeter position.

2-meter folding board—Two 1-meter boards may be connected by a hinge.

Double meter boards 2 meters in height are used when shrubs or other vegetation exceeds the height of a 1-meter board (fig. 21, part A). They are simply two single meter boards attached by hinges and a barrel bolt so that either the 1- or 2-meter length may be used.

Materials—Prices given are in dollars as of 2001.

	Cost
	<i>Dollars</i>
2 pieces ½ inch, 4-ply plywood, finished on one side, exterior, 1 foot by 4 feet, each @ \$20 per sheet	6
3/16-inch-diameter steel rod, 36 inches long	1
Numbers: 5¼ inches tall, on a reflector, adhesive, 2 packets of 10 (need 2 each of 2, 4, 6, 8)	8
Line or pocket level 4 to 5 inches long	4
Two 16-ounce cans of yellow spray paint, exterior	8
2 strap hinges, heavy duty, 4-inch size	5
1 barrel bolt, heavy duty, 5-inch size	8
Screws:	2
2 line level wood screws #4 ⅝ inch	
9 spike plate wood screws #6 ¾ inch	
1 sheet metal screw #10 ½ inch, placed under barrel bolt (sheet metal for hardness)	
10 hinge wood screws #10 1 inch	
8 barrel bolt wood screws #10 ½ inch	2
1 roll black electricians tape	4
Total	\$46

Construction—Construct two 1-meter boards as discussed previously with one important difference. The top board will **not** be 1 meter 2 centimeters tall. Instead it will be exactly 1 meter tall. The top board has its bottom decimeter mark supplied by the lower (1-meter) board (fig. 54).

Construct the bottom (1-meter) board, with spikes at the base and numerals as shown in figure 51. On the top board, use “2M” at the top instead of “1M”, and add numeral “1” to each of the decimeter numbers as shown in figure 54. The numeral “1” may be made from electricians tape. The top board will **not** have a decimeter bar at its base; this bar is supplied by the bottom board.

Hinge system—Figure 55 illustrates the hinge, barrel bolt, and position of the line level between the two halves of the meter board. The barrel bolt holds the boards open and prevents them from flopping in wind.

1. Refer to figure 55. First, measure thickness of the barrel bolt. Cut plywood from the same thickness as the barrel bolt and glue to both meter board halves. The 5-inch bolt shown in figure 55 required 3/8-inch plywood. These plywood blocks separate the meter board halves when folded so that the barrel bolt will clear both its connecting strap and the line level.
2. Attach the hinge straps to the top board first. Use a straight edge to align both meter board halves in a straight line, then attach the bottom straps to the bottom board while holding both halves firmly together.

Figure 54—The 2-meter board system. In the top photo, a standard 1-meter board is shown with the 2-meter half folded under it. In the bottom photo, the folded board has been turned over showing the 2-meter section. “No dm mark” designates the lack of a decimeter mark at the base of the top board; it is at the top of the 1-meter board shown directly above. Length of the 2-meter section must be 2 centimeters shorter (exactly 1 meter instead of 1 meter 2 centimeters) than the 1-meter board to account for this decimeter mark.

Figure 55—Hinges and a barrel bolt connect the two meter boards. (A) When installing hinges, attach to the top board first, carefully align the boards in a straight line, then attach the lower straps of the hinges. (B) The barrel bolt should be oriented to fall down when the board is unfolded. Position the bolt and its strap at the edges of the board halves so that the bolt protrudes about $\frac{3}{8}$ inch below the strap. (C) Install an adjusting screw (see fig. 56) to force the barrel bolt against its strap to stiffen the two boards when unfolded. (D) A line level is placed an inch (2.5 cm) below the barrel bolt on the lower board half so that it can be seen from above when the boards are folded and from behind when they are unfolded as shown.

Figure 56—Adjusting screw and washer used to remove play between the barrel bolt and its strap to stiffen the two halves of a 2-meter board when unfolded. (A) Measure distance between the bolt and the board. (B) Insert a round headed sheet metal screw with enough washers to make the bolt fit firmly under the strap. Sheet metal screws are preferred because of their hardness. Pound the flange down if necessary.

3. Install the barrel bolt next (fig. 56). Position the barrel bolt at the very bottom of the top meter board so that the bolt drops down when the boards are erected. Place the barrel bolt strap as close to the top of the bottom board as possible without screws splitting the wood (fig. 55). The bolt should protrude about $\frac{3}{8}$ inch below the strap. Insert a sheet metal screw under the bolt end with sufficient washers to hold the bolt firmly against the strap. This will prevent flexing of the erected boards (fig. 56).
4. Position the line level on the bottom (1M) board where it can be seen from above when the boards are folded for 1-meter use, and from the back when unfolded for 2 meters (fig. 55). One can see the line level with boards folded by viewing down through the strap into which the barrel bolt drops.

Folding 1-meter board—If field transportation of a meter board is a concern, the 1-meter board can be made to fold at the 4-decimeter mark. The hinge system is described and shown in figures 55 and 56. Figure 57 illustrates dividing the board at 4 decimeters to provide protection for the spikes.

Photograph Identification Sheet Holder

Each photograph taken in photo monitoring should be identified. General and topic photos taken of the meter board are identified by a form attached to a clipboard and positioned between the camera and meter board. The clipboard and an adjustable post to hold it are described.

Clipboard—The clipboard is shown in figure 58. It is a standard 12-inch (30-cm) clipboard with the addition of a second clip removed from another clipboard and attached by rivets or screws as shown. The critical factor is to place the clips no closer than 10½ inches (26 cm) apart to avoid covering any information on the identification paper. Two clips are required to prevent the identification sheet from blowing in the wind.

Figure 57—Folding 1-meter board concept. (A) Cut a standard 1-meter board at 4 decimeters and install hinges and a barrel bolt. This offset is used to protect the spikes as shown in (B). Assemble the board before painting and application of decimeter marks to assure correct measurements.

Figure 58—Clipboard for displaying photo identification forms. It includes a second clip (A) taken from another clipboard that is either screwed or riveted in place. Distance between the clipboard clips should be 10½ inches (26 cm) to (1) hold the sheet in windy conditions, and (2) not cover essential information. The clipboard is placed on the ground for plot photos or on top of a clipboard post (fig. 59) to be set in front of the camera. When placed on the post, a screw (B) inserted into the wooden block holding the ¼-inch rod behind the clipboard (figs. 58 and 61) prevents the clipboard from rotating in the wind. The form shown, "Camera-Photo" (app. A), is used for general photography.

Figure 59—The clipboard post (A) in its compressed position ready to be inserted into straps behind the clipboard. A 1/4-inch rod slides into two 1/4-inch straps on the clipboard. (B) These straps are positioned 4 1/2 inches (11.4 cm) apart and riveted (as shown) or bolted to the clipboard with 1/8-inch rivets or bolts.

Materials—Prices given are in dollars as of 2001.

	Cost
	<i>Dollars</i>
2 clipboards 12 inches long @ \$4.50 each; second clipboard for its clip	9
6 each 1/8-inch diameter bolts or rivets to attach the clipboard clip and straps for the clipboard post	1
2 each 1/4-inch line guides or straps	1
Total	11

Construction—Remove the clip from the second clipboard and attach it to the first with either two bolts or two rivets (fig. 58).

Clipboard post—The clipboard post is an adjustable pole 1 inch in diameter with a spike on the end to be placed in the ground, a telescoping inside pole, and a rod at the other end on which the clipboard is placed (fig. 2 in part A; figs. 59 to 61). It is composed of telescoping plastic pipes each 18 inches (45 cm) long (fig. 60). It is 22 inches (56 cm) long when compressed and 32 inches (81 cm) long when extended. An adjustable hose clamp is attached to the upper end of the larger pipe, which compresses around the inside pipe to hold it in place (fig. 61).

Figure 60—Construction details for the photo identification clipboard post. In (A), 1-inch PVC pipe CL 200 and 3/4-inch PVC pipe CL200, which fits inside the 1 inch pipe, are each 18 inches (46 cm) long. When the 3/4-inch pipe is inserted into the 1-inch pipe and compressed, they are 22 inches long (56 cm). In (B), the 18-inch inside pipe has been extended 14 of its 18 inches (36 of its 46 cm), increasing the length to 32 inches (81 cm). The 1/4-inch diameter spikes at the bottom and top both extend 5 inches (12.7 cm) beyond the pipe and are imbedded into doweling inserted in the pipe.

Materials—Prices given are in dollars as of 2001.

	Cost
	<i>Dollars</i>
PVC pipe 1 inch CL 200 at \$1 per 10 feet	1
PVC pipe 3/4-inch CL 200 at \$1 per 10 feet	1
Hose clamp 1-inch diameter	1
Steel rod 1/4-inch diameter, 36-inch piece, cut two 7 inch pieces	1
Electricians tape	1
Total	5

Construction—Figure 59 illustrates the clipboard post in its compressed position. Two straps capable of having a 1/4-inch-diameter rod inserted are attached to the back of the clipboard at the middle, as shown. They are centered 6 inches (15 cm) from each end and placed 4 1/2 inches (11 cm) apart so that the 5-inch (13-cm) rod will engage each.

Figure 61—Details of how the clipboard is placed over the rod as viewed from the edge of the clipboard. (A) The clip of the clipboard. (B) The edge of the clipboard, in this case an aluminum board. (C) The $\frac{1}{4}$ -inch straps into which the $\frac{1}{4}$ -inch rod of the post is inserted. (D) The $\frac{1}{4}$ -inch rod of the post inserted into the clipboard straps. (E) A screw is inserted into the wood doweling that holds the $\frac{1}{4}$ -inch rod. The screw prevents the clipboard from rotating in the wind (fig. 58). (F) A piece of doweling fitted inside the $\frac{3}{4}$ -inch PVC pipe is drilled out for a $\frac{1}{4}$ -inch steel rod and is held in place by a screw. (G) With a saw, cut down 2 inches (5 cm) into the 1-inch PVC pipe so that the pipe can be compressed by the hose clamp (H) to hold the inside pipe at the desired height. At (H), secure the hose clamp with electricians tape.

The clipboard post is composed of two parts (fig. 60). One is 1-inch CL 200 PVC pipe and the other is $\frac{3}{4}$ -inch CL 200 PVC pipe, both 18 inches long. The $\frac{3}{4}$ -inch pipe fits inside the 1-inch pipe with some slack. If pipe specifications other than these are used, be sure that one pipe will fit inside the other. When compressed, the clipboard holder is 22 inches (0.5 m) tall. When extended with 4 inches of interior pipe inside, it is 32 inches (0.8 m) tall (fig. 60).

To make the clipboard post adjustable, saw down 2 inches (5 cm) into the upper end of the 1-inch pipe (fig. 61). Then attach a 1-inch hose clamp an inch below the top of the pipe and secure it with electricians tape. Tighten the hose clamp so that the inside $\frac{3}{4}$ -inch pipe can just be moved up and down to adjust height of the clipboard above vegetation or other obstructions.

Figure 62—A leveling board for taking photos of tree canopy cover directly overhead measures 4½ by 6 inches (11.2 by 15.3 cm) and has a two-way level attached. It is made from scrap ½-inch plywood.

Figure 63—The camera leveling board is used to take repeat photographs of the tree canopy with some consistency. Place the leveling board on top of the meter board for consistent height above the ground. Place the meter board at right angles to the photo view. Move the meter board sideways to center the cross-view bubble, then tilt the level board to center the down-view bubble, move your head back, and photograph.

Camera Leveling System

Photographs taken by looking up at the tree canopy require a camera leveling system for consistent repeat photography. A leveling system described here uses the top of the meter board as one axis for consistently orienting the camera and a leveling board for the other axis (fig. 62). Figure 62 illustrates the camera leveling board and figure 63 illustrates use of the board.

Materials—Prices given are in dollars as of 2001.

	Cost
	<i>Dollars</i>
One two-way level or two line levels	4
Scrap piece of ½-inch plywood 4 by 6 inches (10 by 15 cm)	—
Total	4

Figure 64—Double camera bracket for use when photographing in both color and black and white. The bracket is made from 1-inch by $\frac{1}{8}$ -inch aluminum bar-stock with holes drilled to mount the cameras. Identical cameras are recommended to simplify camera adjustments. Figures 65 and 66 illustrate construction details.

Construction and use—Figure 62 illustrate the dimensions of the camera leveling board and placement of the two-way level. Figure 63 illustrates use of the leveling board. Place the board on top of the meter board, move the meter board left or right to center the cross-view level, then tilt the board to center the down-view level. Move your head out of the way and photograph.

Double Camera Bracket

Two cameras reduce complications when photographs are needed in both color and black and white. A bracket to hold both cameras together allows for simple and effective manipulation of the cameras (fig. 64), and identical cameras simplify adjustment. When ready to photograph, simply shoot with the top camera, then the bottom, and advance the films.

Figure 65—The double camera bracket (A) with thumb screws to attach the cameras. Washers may be required if thumb screw shanks are too long. (B) Thumb screws come in two parts: the shank in several lengths and thread sizes, and the head. The head must be forced onto the shank by using a vise (C). A shank diameter of 1/4 inch, length of 3/8 inch, and 20 threads per inch fits many cameras.

Materials—Prices given are in dollars as of 2001.

	Cost
	<i>Dollars</i>
Aluminum bar stock 1 inch (2.5 cm) wide by 1/8 inch (3 mm) thick, @ one 6-foot piece (will need 18 inches [45 cm])	8
Two instant thumb screws:	
Shank 1/4-inch diameter, standard 20 thread, 3/8 inch long (2)	1
Instant thumbs (2)	1
Total	10

Construction—The aluminum bar stock, cut into an 18-inch (45-cm) piece, is bent into equal 6-inch (15 cm) segments to form a "U" (fig. 65). Then 1/4-inch holes are drilled 2 1/2 inches (7.5 cm) in from the ends (fig. 66) to hold the cameras. Make sure the holes hold the camera in such a position as to make the rewind button available (fig. 66B).

Figure 66—Two factors are important in attaching a camera to the bracket. (A), Make two cuts $\frac{1}{4}$ of an inch deep and $\frac{1}{2}$ inch apart into the front of the bracket. Bend up to about a 30-degree angle to prevent rotation movement of the camera. (B) Make sure the bracket clears the rewind button so that film may be changed while the camera is attached to the bracket.

Next make two $\frac{1}{4}$ -inch (6 mm) cuts $\frac{1}{2}$ inch (12 mm) apart into the aluminum toward the front of the camera and bend the $\frac{1}{2}$ -inch piece upwards to about a 30-degree angle (fig. 66A). Do not bend more than 30 degrees or the aluminum will break. These will prevent the cameras from rotating on the bracket.

Finally, assemble the thumb screws, which come in two parts: the shank and the thumb head. Make sure the shank will fit the camera mounting socket. Usually a $\frac{1}{4}$ -inch diameter, 20-thread shank $\frac{3}{8}$ inch long will work. Press the head onto the shank as shown in figure 65C by using a vise. Generally, heavy pliers do not apply sufficient force to seat the thumb head.

Figure 67—Orange identification tag used to mark photographic monitoring sites. Inscribe, with a carbon point instrument, the monitoring identification name or number, date, person installing the system, and direction and measured distance to key items, such as camera locations or photo points. Mount the tag on a witness post or tree specified in the map on the "Photographic Site Description and Location" or "Sampling Site Description and Location" form.

Orange Identification Tags

Photo monitoring sites may be identified in the field by an orange tag attached to a witness post, tree, or other item identified on the sampling location maps. One kind of tag is shown in figure 67. It was custom printed for use with ecology plots. Other formats are available. The sign in figure 67 costs \$1.45 each in minimum lots of 50. New, custom printing costs \$20 for set up (prices in 2001). They may be obtained from:

Flimsy Fenceposts

My preferred system for marking camera locations and photo points is flimsy, stamped metal fenceposts 5 feet (1.5 m) long (fig. 68). They are preferred over strong, T-bar posts for several reasons: (1) they are low in cost, about \$2.50 each; (2) they are lightweight such that four or five may be carried for the weight of one

Figure 68—Flimsy stamped metal fencepost used to mark camera locations and photo points. Flimsy means the post can be twisted by hand. A 5-foot (1.5-m) length allows for pounding it 2 feet (0.6 m) into the ground, which tends to deter theft because the effort needed to remove it is not warranted by the post's value.

T-bar; (3) they are easy to pound, and the pounder weighs half of that used for T-bar; (4) of this 5-foot length, about 2 feet is in the soil when the top is even with a meter board, sufficient to require more effort to remove than the flimsy post is worthy of, thus deterring theft; (5) the flimsy strength means an animal can run into it and only be scratched, not impaled, or it can be driven over with minimum vehicular damage; and (6) the post will bend flat with the ground and remain in place when crushed by ice, logs, animals, or vehicles instead of being pulled out.

These posts are available at many large building material stores. My supply is through Home Depot. The manufacturer is Keystone Steel and Wire, 1-800-447-6444; select "Sales" from their menu, and ask for the representative in your area (such as Oregon) for a sales outlet. Ask for "5-foot, **light** duty, stamped metal fenceposts." They are also manufactured in medium duty, which are about an inch broader and stronger, an unnecessary attribute. The "light duty" posts probably will have to be ordered because they have limited usefulness.

The **Forest Service** of the U.S. Department of Agriculture is dedicated to the principle of multiple use management of the Nation's forest resources for sustained yields of wood, water, forage, wildlife, and recreation. Through forestry research, cooperation with the States and private forest owners, and management of the National Forests and National Grasslands, it strives—as directed by Congress—to provide increasingly greater service to a growing Nation.

The U.S. Department of Agriculture (USDA) prohibits discrimination in all its programs and activities on the basis of race, color, national origin, gender, religion, age, disability, political beliefs, sexual orientation, or marital or family status. (Not all prohibited bases apply to all programs.) Persons with disabilities who require alternative means for communication of program information (Braille, large print, audiotape, etc.) should contact USDA's TARGET Center at (202) 720-2600 (voice and TDD).

To file a complaint of discrimination, write USDA, Director, Office of Civil Rights, Room 326-W, Whitten Building, 14th and Independence Avenue, SW, Washington, DC 20250-9410 or call (202) 720-5964 (voice and TDD). USDA is an equal opportunity provider and employer.

Ground-Based Photographic Monitoring

Frederick C. Hall

Author

Frederick C. Hall is senior plant ecologist, U.S. Department of Agriculture, Forest Service, Pacific Northwest Region, Natural Resources, P.O. Box 3623, Portland, Oregon 97208-3623. Paper prepared in cooperation with the Pacific Northwest Region.

Abstract

Hall, Frederick C. 2001 Ground-based photographic monitoring. Gen. Tech. Rep. PNW-GTR-503. Portland, OR: U.S. Department of Agriculture, Forest Service, Pacific Northwest Research Station. 340 p.

Land management professionals (foresters, wildlife biologists, range managers, and land managers such as ranchers and forest land owners) often have need to evaluate their management activities. Photographic monitoring is a fast, simple, and effective way to determine if changes made to an area have been successful. Ground-based photo monitoring means using photographs taken at a specific site to monitor conditions or change. It may be divided into two systems: (1) comparison photos, whereby a photograph is used to compare a known condition with field conditions to estimate some parameter of the field condition; and (2) repeat photographs, whereby several pictures are taken of the same tract of ground over time to detect change. Comparison systems deal with fuel loading, herbage utilization, and public reaction to scenery. Repeat photography is discussed in relation to landscape, remote, and site-specific systems. Critical attributes of repeat photography are (1) maps to find the sampling location and of the photo monitoring layout; (2) documentation of the monitoring system to include purpose, camera and film, weather, season, sampling technique, and equipment; and (3) precise replication of photographs. Five appendices include (A) detailed instructions for photo sampling, (B) blank forms for field use, (C) specifications and photographs of recommended equipment, (D) filing system alternatives, and (E) suggestions for taking photographs and analyzing change over time.

Keywords: Monitoring, photographs, landscapes, transects, animal sampling, riparian, succession, forests, rangeland.

Preface

This document started as an update of my 1976 publication on photo monitoring to appraise rangeland trends. The update was stimulated by a desire to document 40 years of experience in rephotography. This included about 150 ecology sample plots rephotographed at 5- to 10-year intervals, 25 years of herbage production, 25 years of riparian change photographed three times per season, and up to 40 years of rephotography of about 80 other situations, including wildfires, prescribed fires, tussock moth and spruce budworm damage, mountain pine beetle effects on lodgepole and ponderosa pine, fenceline contrasts between good and poor range condition, logging, revegetation, research studies and various landscape views. There is a great breadth of ground-based photographic monitoring in the literature. One aspect I found was use of photographs to estimate various existing conditions of vegetation and soil, such as comparison photo monitoring following Maxwell and Ward's (1976a) guides to estimate fuel loading, fire intensity, rate of spread, and resistance to control. Another was use of remotely controlled cameras to monitor presence of animals as illustrated by Kristan and others' (1996) video monitoring of osprey nest activities. And finally, repeat landscape photography of pictures taken at the dawn of cameras and exploration of the west, as exemplified by Progulske and Sowel's (1974) rephotography of Colonel Custer's exploration of the Black Hills in 1874—100 years of change. It is hoped that the information gained by personal experience and literature review will provide some guidelines for successful ground-based photo monitoring.

Introduction

Ground-based photographic monitoring is designed for use by land managers, such as foresters, wildlife biologists, range managers, ranchers, and forest land owners. It is a way to document management activities and evaluate changes. For many people, photographs are faster and easier to interpret than measurements, and measurements, if needed, can be made from the photographs.

The system uses cameras at ground level rather than aerial photography or other aboveground sensing. It includes several applications using either still picture or video media. For example, fuel loading conditions found in the field can be compared with photographs of known fuel characteristics to estimate tonnage per acre, flame length, rate of spread, and control problems; this is known as *comparison photo-graphy*. Or, cameras can be remotely controlled to document animal activities, which is *remote photography*. Camera locations also may be established and the same scene rephotographed periodically for *repeat photography*. Photographs produce a unique kind of monitoring not duplicated by measurement or inventory systems, although photography is subject to requirements that limit its application and use.

I begin with definitions and concepts, then discuss items common to all photography, followed by comparison photo monitoring, remote photography, repeat photography, and end with relocation of photo monitoring sites.

Definitions

Discussion of ground-based photo monitoring should start with a few definitions:

Monitoring is detecting change or condition of various topics. In this paper, it includes detecting change in riparian shrub cover, healing of disturbed soil, identifying presence of animals, documenting air quality, or estimating condition of some item such as fuel loading or percentage of utilization of herbage.

Photography refers to photographs or video or digital images, color or black and white, taken or used at the site, as opposed to aerial photograph interpretation and Landsat image analysis. The concept of ground-based photo monitoring therefore means using photographs taken on the ground to evaluate change or condition of various items.

Camera format specifies a focal length of the lens and ultimate image size. Some common formats are 50-mm lens on a 35-mm camera, 70-mm lens on a 2- by 2-in camera, or a 128-mm lens on a 4- by 5-in camera. All are comparable insofar as what part of the landscape is included in the final image. Formats may differ for the same camera. A zoom lens on a 35-mm camera can change from 35-mm focal length wide angle to 110-mm telephoto. Most photographs in this publication were taken with a 35-mm camera and a 50-mm lens.

Three terms are used to identify types of photography:

Landscape photographs are of distant scenes or of a broad, general area often more than 10 ha.

General photographs document a topic being monitored and commonly cover 0.25 to 10 ha. They may be used alone or in conjunction with closeup photographs.

Closeup photographs are made of a specific topic on a small tract of ground often from a few decimeters to 10 by 10 m. They have no horizon reference, and the locations from where the photographs are taken therefore must be marked with stakes or fenceposts.

Finally, three terms are important in photographic sampling systems:

Witness site is an easily identified reference used to locate the monitoring area. It provides compass direction and distance to the camera locations.

Camera location is a permanently marked location for the camera.

Photo point is the direction of the photograph from the camera location. It is marked permanently by a steel stake or fencepost and commonly involves a size control board located in the center of the photograph. More than one photo point may be taken from a single camera location, and more than one camera location may photograph a single photo point.

Comparison and Repeat Photography

Comparison—In comparison photo monitoring, existing conditions are compared with conditions shown in a set of photographs. For example, Maxwell and Ward (1976a) produced a color photograph field guide for estimating logging fuel loading in tons per acre by size class with estimates of fire intensity, rate of spread, flame length, and resistance to control. Kinney and Clary (1994) developed a guide for estimating the percentage of utilization of riparian grasses and sedges by using photographs of various stubble heights. And Magill (1990) evaluated public concern over logging by having people rate a set of color landscape photographs taken at different camera focal lengths to simulate various distances from the scene.

Repeat—Repeat photography is characterized by taking multiple photographs of the same landscape, tract of ground, or activity, such as animal presence. It's particularly useful in three situations:

1. Landscape photography, where change is documented for landscape-sized areas over time. Some classic examples are Progulske and Sowel's (1974) documentation of Colonel Custer's exploration of the Black Hills wherein they rephotographed pictures taken in 1874. Another is panoramic photography using special camera equipment to take 360-degree views of landscapes, as Arnst (1985) shows for the Cascade Range of the Pacific Northwest.
2. Remotely operated cameras used to monitor animal behavior such as that of nesting ospreys (Kristan and others 1996), evaluate air quality (Fox and others 1987), or document animal distribution (Kinney and Clary 1998).

3. Site-specific repeat photography identifies specific topics on selected tracts of ground to document change or lack of change in vegetation and soil. Gary and Currie (1977) show a 40-year record of plant and soil recovery on an abused watershed in Colorado, and Smith and Arno (1999) document 88 years of change in managed ponderosa pine forests through 14 camera locations.

Clearly, photo monitoring is not a simple, routine procedure, but rather a multifaceted concept covering various purposes or objectives. To discuss this topic, the paper is organized into seven main parts: items common to all photo monitoring, comparison photos where current conditions are compared to a series of photographs and their condition rated, repeat photography of landscapes, photo monitoring by remotely operated cameras, site-specific repeat photography, and lessons in relocation of repeat photography.

The appendices cover many items in detail: Appendix A gives the methodology for monitoring change in vegetation and soil, appendix B contains blank forms for both office and field ready to copy, appendix C has plans for construction of meter boards and plot frames, appendix D discusses filing systems for photo monitoring, and appendix E illustrates photographic tips.

Common Items

Common to all photographic monitoring are (1) determining specific objectives, (2) using a repeatable technique, (3) choosing appropriate camera and film, and (4) developing a filing system.

Select Specific Monitoring Objectives

The first and most important item in any monitoring project is to have specific objectives. Questions answerable by photography must be asked before any kind of monitoring can be developed and installed. Consider a five-part query to develop these objectives: why to monitor, where to locate the sampling, what specific topic to evaluate, when to do the photography, and how to accomplish the photography (Borman 1995; Nader and others 1995; U.S. Department of the Interior, Bureau of Land Management 1996).

Why—Why to monitor asks for definition of the question needing an answer. Implementation monitoring asks if what was done was what was indicated, effectiveness asks whether the treatment did what was wanted, and validation asks if the treatment met the objectives. *Why* sets the stage for all other questions.

Where—Where to monitor depends upon the *why*. Where will the selected representative tracts, animal activity areas, treatment sites, or particular kinds of treatments be located? Will number, size, and location of activities such as fire, logging, revegetation, livestock grazing or flood affect the selected site(s)? Ask where the best location is that will answer the questions. Critical documents are a map to locate the site and a site map to document all camera locations and photo points.

What—Which items on the selected tract—vegetation, soil, streambanks, animals, air quality—will be monitored to support the *why*? Ask what the critical few items are that must be documented. What is expected to change? What will the picture demonstrate? Why should I take this picture (Johnson 1991)? The *what* dictates sampling layout.

When—When to monitor supports the *why* and *what* questions. Does monitoring encompass one year or multiple years? One season or more? Specific dates and time(s) of day? All are important in both animal and site monitoring. Scheduling includes time before treatment as well as after and frequency after initial treatment. Unplanned disturbances, such as fire or flood, pose special problems. A monitoring protocol may have to be developed on the spot to determine when and where during the event to establish photo points and to define a followup schedule.

How—How to monitor is determined by *what*, *why*, and *when*. It encompasses detailed protocols for photographic procedures used to obtain qualitative data (estimates) or quantitative data (measured in the field or measured on photographs). (Appendix B contains detailed instructions for both systems.) An example might be dealing with effects of livestock grazing on a riparian area: (1) Are streambanks being broken down? (2) Are riparian shrubs able to grow in both height and crown spread? (3) Is there enough herbage remaining after grazing to trap sediments from flooding? (4) Is herbaceous vegetation stable, improving, or deteriorating? Answering these questions will require selection of a sampling location and establishment of photo points and camera locations sufficient to gather adequate data. Try to select camera locations that will photograph more than one photo point. The time or times of year to take photos then must be specified, such as just prior to animal use of the area, just after they leave, or fall vegetation conditions. Will this riparian site be monitored for high spring runoff, late season low flows, or during floods? Monitoring of stream flows probably requires different scheduling from monitoring of animal use.

Repeatable Photo Technique

A second common item in photo monitoring is a repeatable technique that can be used by various people to attain similar results. For a technique to be repeatable, it must be simple, thoroughly documented, and illustrated. The following items are key elements in a well-documented and -illustrated technique:

1. A map locating the photo monitoring site and one or more maps of the photo monitoring layout for the site.
2. Camera locations and photo points permanently marked with steel fenceposts or iron stakes. Iron stakes should be flush with the ground to prevent tire and foot (hoof) damage. They are difficult to relocate but can be found with a metal detector. Positions of camera location and photo points are critical (Rogers and others 1983). The need for a constant distance between camera and photo point for all repeat photography is demonstrated under "Camera Format," below.

Figure 1—Landscape used to test effects of camera format (focal length), distance from camera to photo point (meter board), and camera position on size and location of items. Camera format is 35-mm using three focal lengths (lenses): 35-mm wide angle, 50-mm standard, and 70-mm telephoto. Distances are 7, 10, and 14 m. Camera positions are eye level (1.8 m), breast height (1.4 m), and offset right by 4 dm. Numbered items are outlined and compared: (1) bucket between camera and meter board, (2) double meter boards, (3) log on the ground, (4) root wad, (5) cart 15 m from the meter board, and (6) lamp pole 50 m from the meter board. Four situations will be evaluated: (A) varying the distance from camera to meter board but using the same focal length camera (figs. 2 and 3); (B) varying both distance and focal length such that the meter board is the same size in all pictures (figs. 4 and 5); (C) varying the camera focal length at a given distance (figs. 6 and 7), and (D) varying camera position over the camera location fencepost (figs. 8, 9, and 10).

3. Precise description, by time of day, weather, and season, of when landscape or general and closeup scenes are to be photographed—all are directly related to the objectives for monitoring; for example, before 10 a.m. and after 3 p.m. if back-lighted vegetation is needed (app. E), visibility of 25 or more miles for repeat landscape photography, high overcast to avoid shadows in forest photography (app. E), bird monitoring in spring, livestock grazing at mid or late season, or documenting high and low stream flows in spring and late summer. Special instructions, such as key landscape items to identify in landscape photography, also are needed.
4. A description of how to photograph and show camera locations and photo points on the site map. A size control board (fig. 1; app. C), such as a meter board, is needed for general photos and appropriate plot frames for closeup photos (app. C).
5. Suitable forms and field instructions for accomplishing the monitoring (apps. A and B).

6. An equipment list including a specified camera and film, field forms to be used in each photograph, any needed measuring or calculating equipment, and fence-posts and equipment to permanently mark photo locations. Specify whether a tripod is required and why.
7. Specific, detailed diagrams and instructions for installing and maintaining photographic equipment. This is particularly important with remotely operated camera systems to assure their proper functioning.
8. A comprehensive filing system (app. D; Johnson 1991, Nader and others 1995) with a container for each study to hold all information: monitoring objectives, site descriptions, maps, color slides, and black-and-white pictures with their negatives or digital memory cards with a copy of the images. All color slides, black-and-white pictures plus their negatives, and digital images and their memory cards need to be labeled immediately after processing. A note on the outside of the file of the last monitoring date is helpful.

Cameras and Film

The purpose of photo monitoring is to document change in a landscape or topic over time. Measuring change requires photographs of good to excellent resolution and color, both of which are influenced by camera and film.

Two kinds of cameras are available: film and digital. Each has specified formats, such as a film camera with 35-mm film with a 50-mm lens, which is similar to a digital camera with a 13-mm lens. Some photographers suggest that changing from one kind of camera format to another poses serious problems in matching photographs. This is not insurmountable, however, as discussed under “Camera Format,” below. Another concern is quality of image. Switching from one brand of color film to another tends to change tones, particularly green and blue. And changing from film to digital usually influences image resolution and color.

Film and digital camera characteristics—Both types of cameras come in two configurations: (1) viewfinder and (2) view-through-the-lens or single lens reflex (SLR). Many digital cameras use SLR principles with a liquid crystal display (LCD). An LCD is a miniature (about 25 by 37 mm) computer monitor screen that displays the image as seen through the lens (Kodak 1999b). Viewfinders show an image that is parallel with the lens and have an outlined box in the viewer to show what the image will cover when a picture is taken at close range (parallax correction). The image will always appear sharp. With SLR systems, the image is viewed exactly as it will appear: there is no parallax correction and the image will appear fuzzy when out of focus, but SLR cameras are more expensive.

Both film and digital cameras provide for a strobe flash system. Less expensive cameras often have built-in flash that fires straight ahead and is effective within 2 m for direct light and within 6 m for fill-in. More expensive cameras provide a “hot shoe” for attaching a more powerful and adjustable flash system. Additional flash systems add cost to the camera. Some cameras provide both an internal flash and a hot shoe.

Zoom lenses have become popular, particularly with the point-and-shoot automatic 35-mm cameras. They also seem to be common on many digital cameras. These lenses have two main attributes: they add flexibility to the camera and they tend to be less sharp than a fixed lens. Zoom lenses may pose problems in photo monitoring because of the need to set a precise focal length to reproduce the original image coverage. For an SLR lens, this isn't too difficult because the lens will have focal lengths marked. But a point-and-shoot 35-mm camera will zoom from 35-mm focal length to 100 mm or greater, a threefold difference in photo coverage, with no indication of the precise focal length used. The equivalent in digital cameras would be 9.2 mm to 28 mm. See "Camera Format" for details.

Lens quality and speed vary. Lens speed is given in f-stops. The "f" indicates how large a hole is open to admit light into the camera. Small f-stops admit much light and large f-stops admit little: for example, at f-3.5, two times more light is admitted than at f-5.6, and f-5.6 admits twice the light of f-8. Depth of field also increases with an increase in f-stop. A slow lens of moderate sharpness is often characterized by f-stops of 3.5 to 4.8 and fast lenses of good sharpness by f-stops of 1.2 to 2.4. A film camera with an f-3.5 lens that's wide open and shooting at 1/60 of a second will create an underexposed image if the light meter says f-2.4 is needed, but a camera with an f-1.2 lens can easily capture the image. Faster lenses are more expensive. The processing unit in the camera computer usually provides digital camera speed; faster speed costs more.

Resolution (sharpness of the image) in film cameras is a function first of lens quality and second of film speed, which translates to graininess in the final picture. The difference in cost for films between ISO 100 and 400 is minimal, but good lenses do cost more. In digital cameras, resolution is determined by maximum dpi (dots per inch) of the camera. As of January 2000, most digital cameras started at about 0.7 megapixels, suitable for 4- by 6-in snapshots, and go up to 3.6, appropriate for 11- by 14-in pictures. Do not use less than a 2-megapixel camera. Good quality optical lenses also enhance resolution. Most digital cameras offer a choice of three to five resolution levels. For example a 1.3-megapixel camera might offer its best resolution at 1280 by 1020, midresolution at 900 by 700, and lowest at 600 by 400. Finer resolution results in fewer images on a digital storage card and slower processing. Quality also is influenced by the kind of compression, if any, used to store the image, and compression influences how many images may be placed in a memory card.

Film and digital concepts—One might consider the digital camera a special purpose computer designed to take photographs (Kodak 1999b). Digital images are captured on an electronic storage, or memory, card that must be processed to produce an image. The camera can alter an image with different settings. Images are made up of dots called pixels, each composed of three colors: red, green, and blue. Intensity of each color can be adjusted. Film and digital storage cards are discussed shortly.

A camera using slide film exposes an image on film—*period*. Once the exposure is made, there is no recourse with correction. There is some recourse with black-and-white and color negative film by changing print exposure time, selection of paper, and dodging or burning items to be enhanced.

With digital cameras, the image is only one link in the chain to a photograph (Kodak 1999a): This chain is (1) the camera with its dpi or pixel resolution, lens quality that captures the image, and the camera's ability to modify pixel characteristics; (2) CPU (the computer) that processes the image with its ability to make major changes in the pixels and thus the image; (3) monitor with its color projection of the image on the screen, which is used as a basis for changing the image characteristics; and (4) the output device that either prints the image (printer) or projects it (projector). The camera, CPU, and output device affect the resolution (dpi), color quality, and contrast. Matching the camera resolution with that of the CPU and output device attains best image quality. They are **not** all the same.

Film speed, the amount of light required to expose the film, is characterized by an ISO rating. Film resolution (graininess of an image) also is a product of film speed: faster film has more grain. Common ISO ratings are 100 for slow speed and fine-grain film (for example 1/60th second at f-5.6); ISO 200, which can be shot at twice the shutter speed (1/120th second at f-5.6) and has medium graininess; and ISO 400, which can be shot at four times the shutter speed (1/250th second at f-5.6) but is rather coarse grained.

Digital camera equivalents are approximately 1640 by 1400 dpi for ISO 400 (2.4-megapixel camera), 1960 by 1600 dpi for ISO 200 (3.2-megapixel camera), and 2280 by 1800 dpi for ISO 100 (4.1-megapixel camera). To determine the camera rating, multiply the two pixel numbers: $1280 \times 1020 = 1.3$ megapixels.

Output (pictures) differs between film and digital cameras. The prints are similar because they are all images printed on paper. Prints from color and black-and-white film and from digital images all share the same result: a picture one can hold in their hand or mount on a monitoring form.

Slides made from film and digital images share few common traits, however. A film image is determined at exposure and can be shown in presentations through a slide projector. A digital image cannot. Generally, the digital image first must be downloaded from the camera and placed into memory of a laptop computer. Then the laptop must be connected to a digital projector for presentation. Recently, cameras have been programmed for download directly to a projector; however, this projects only slides in the camera. It does not provide for a presentation using title, data, and instructional slides. Here are some things to consider when projecting digital images for a presentation (Kodak 1999a):

1. Know the native resolution (dpi) of the laptop and the camera. Select the resolution that will support "high color" (16 bit) color depth (1280 by 1024 dpi; a 1.3-megapixel camera) or higher. Settings of the laptop computer above or below the camera settings will result in reduced image quality.

2. Match the resolution of the laptop with the resolution of the digital projector. If the laptop uses 1280 by 1020 dpi and the projector only 800 by 600, image quality will be at the projector resolution.
3. Understand that colors on the computer monitor used to modify image characteristics are not the same as those projected. The projector gives the more accurate color.

Film—Film is another consideration in photo monitoring, particularly the use of color slide film compared to negative films when prints are the desired outcome. Prints can be modified many ways by using different kinds of printing paper, exposure timing, dodging, burning, and different filters to make good comparison pictures. An advantage of black and white film is its long life. Most color films or prints tend to fade over the years, even if they are kept in dark, cool, dry locations.

Tones in color film differ according to the chemicals used in manufacturing and processing the film: Kodachrome has warmer, more vivid colors than Elite Chrome (Ektachrome), yet Elite Chrome (Ektachrome) tends to produce a truer reproduction of the greens and browns in a natural landscape.¹ Repeat photography done with different brands of film therefore produce some significant differences in appearance of vegetation conditions in the scene, whether real or not (Magill 1989). The photo monitoring protocol should prescribe the brand of film, speed of film, and light (weather) conditions for the project.

Film processing will influence how well photos can be compared. Most film is sent to a commercial processor where either slides are produced or pictures are printed at a standard size, such as 3½ by 5 or 4 by 6 in. Quality of processing differs. Do not cheapen your product by cutting costs and quality at the final step (Johnson 1991).

Weather should be related to film. How does current weather compare to conditions of previous photographs (Magill 1989, Maxwell and Ward 1980a)? A dense, heavy cloud layer will produce different colors and tones compared to a high, thin overcast, which in turn will be different from full sunlight that causes deep shadows. Maxwell and Ward (1980a) suggest overcast skies to reduce shadows and taking at least three different exposures to bracket light conditions for comparable colors between photos. Weather conditions of original photographs should be duplicated.

Digital storage cards—Digital cameras do not use film, but rather electronic storage cards (Kodak 1999a). Storage cards are not developed but are processed by computer. Any or all images can be erased and the card reused. The color quality, contrast, and depth can be manipulated. Either all images or selected ones can be copied from one card to another, greatly facilitating storage and retrieval of images. Different brands of cameras use different storage cards. Storage cards also come in several sizes and makes.

¹ The use of trade or firm names in this publication is for reader information and does not imply endorsement by the U.S. Department of Agriculture of any product or services.

Storage cards vary in their megabyte (MB) capacity, which directly limits the number of images that can be stored. A general conversion from number of pixels in an image to number of images per storage card is a 1-to-1.2 ratio: a 1-megapixel photo requires about 1.2-MB of storage card capacity. For example, an image at 1280 by 1024 pixels (1.3-megapixels) would require an entire 2-MB card, or 24 photos could be placed on a 32-MB card. The same 32 MB card would hold 66 photos at 800 by 600 pixels (0.48-megapixel).

Digital storage cards can be reused. The deleted images, of course, are lost.

Processing of storage cards is quite different from film, with two alternatives: commercial or home processing. Commercial means the storage card is sent to a digital processing laboratory for prints similar to film. Home processing requires use of a CPU, with a download system from the camera, and a printer. For best image quality, the dpi of the camera and computer should be compatible, and the dpi of the computer and printer also should be compatible. Image quality is sacrificed if either the computer or printer cannot process the dpi of the camera, or image quality may be sacrificed by color rendition of the printer.

Digital images may be stored in three ways: (1) in the memory card used with the camera, (2) transferred to a compact disk (CD) and the memory card reused, or (3) transferred to a computer hard drive with essential information in its file and the memory card reused. If stored in a computer, assure that instructions for locating the folder or file are placed in the photo monitoring filing system.

Color prints are similar in cost between film and digital systems; however, slides made from digital memory cards tend to cost more. The use of two steps, from card to negative and from negative to slide, tends to reduce quality of the image.

Camera Format

Camera format is the combination of camera body image size and focal length of a lens. Format concepts apply to both film and digital cameras. Exact duplication of camera format is not of critical concern (Rogers and others 1983) when evaluating change in the subject photographed. Images may be enlarged or reduced to a constant area of coverage, printed, and compared.

When using slide film, however, images taken with different camera formats will project differently on the screen. This is a major concern discussed by Magill (1989) in his analysis of change in campgrounds. He projected slides onto a screen with a grid and adjusted size of the image according to specified criteria prior to analysis.

Some examples of common film camera formats that cover about the same area of a landscape are (1) 1- by 1.5-in image size (35-mm camera) using a 50-mm focal length lens, (2) 2- by 2-in (50- by 50-mm) image size using a 70-mm lens, or (3) a 4- by 5-in (100- by 125-mm) image using 128-mm lens. All are equivalent to a digital camera at 13-mm focal length. The advent of good quality zoom lenses permits a great variety of camera formats having both desirable and undesirable features.

A desirable feature is increased flexibility in choosing photograph formats without the need to change lenses. Undesirable features include higher f-stops and no constant focal length when rephotographing monitoring sequences.

The effects of camera format and distance from camera to subject are shown and discussed in figures 1 through 7. Camera position concerns are illustrated in figures 8 through 10. Change in emphasis on a topic by distance is discussed in "Camera Techniques," below.

Figure 1 shows a testing landscape where six objects are positioned, photographed, and outlined to compare size and location of the objects with change in distance, focal length, and camera position. Three lenses were used with a 35-mm camera body: (1) 35-mm wide angle, (2) 50-mm as a standard for comparison, and (3) 70-mm telephoto; these are equivalent to digital cameras of 9, 13, and 18 mm. They were used in conjunction with three distances from camera to meter board: (1) 7 m, (2) 10 m as a standard for comparison, and (3) 14 m. The effect of camera position was evaluated at 10 m with a 50-mm lens. The standard for comparison was 1.4 m above the ground (breast height) centered over the camera location fencepost. Camera position was moved upward 4 dm to 1.8 m (eye level) and sideways 4 dm.

The first evaluation (fig. 2) is a standard camera format of 50-mm lens on a 35-mm camera positioned 7, 10, and 14 m from a meter board. All photographs in figure 2 are clearly different. Outlines of objects, adjusted in size to the meter board at 10 m are shown in figure 3. All objects are different in both size and location.

Next, both camera format and distance to meter board were adjusted. The objective was to photograph the meter board at a constant size where the 35-mm lens at 7 m gave the same size meter board as 50-mm at 10 m and 70-mm at 14 m (fig. 4). Notice the difference in backgrounds. Comparison of object outlines in figure 5 shows that all objects are different in both size and location, almost identical with figure 3.

Finally, focal lengths (35, 50, and 70-mm) were changed at a fixed distance, 10 m (figs. 6 and 7). Figure 6 appears to show very different scenes insofar as what is included within each photo. But when the images are adjusted to size of the meter board at 50 mm shown in figure 7, each object is almost exactly the same size and location. This effect is what Rogers and others (1983) discuss. Figures 2 through 7 clearly indicate that distance from camera to meter board is critical; whereas focal length is not.

Text continues on page 20.

Figure 2—Effect of distance from camera to meter board on location and size of outlined objects when using the same camera format. Camera format is a 50-mm length lens on a 35-mm camera at 7, 10, and 14 m from the meter board. Objects were outlined on clear plastic overlay sheets as follows: 10 m in a solid line, 7 m in dashes, and 14 m in dots. Each outline was adjusted in size to match the meter board at 10 m as follows: measure in millimeters from the top of the board to bottom; this measurement is divided into the measure for 10 m for a percentage of change; then enlarge or reduce the overlay by that percentage. (A) The 10-m board was 23.0 mm and 100 percent; (B) the 7-m board was 34.0 mm reduced to 68 percent, and (C) the 14-m board was 16.5 mm enlarged to 139 percent. Figure 3 compares the adjusted outlines.

Figure 3—Overlays of object outlines from figure 2 adjusted in size to 10 m. The 10-m outline is solid, 7 m is dashes, and 14 m is dots. (A) Overlays of 7 m and 10 m shows objects of different size and location. (B) The 10-m and 14-m overlays also show different sizes and locations. (C) All three overlaid show that all objects are different in both size and location. Distance from camera to meter board is critical if objects in photographs are to be compared.

Figure 4—Both focal length and distance to meter board are adjusted to make the meter board the same size in each photograph: (A) 50-mm at 10 m, (B) 35-mm at 7 m, and (C) 70-mm at 14 m. Meter boards are measured to show similarity, and outlines were adjusted by the percentages shown. Objects are outlined on clear plastic overlays as follows: 50-mm with a solid line, 35-mm in dashes, and 70-mm in dots. Notice how the backgrounds change with a constant size meter board. Figure 5 compares the object outlines.

Figure 5—Object outlines from figure 4 overlaid to evaluate effects of camera focal length and distance from camera to meter board on size and location of objects. Photos were taken to keep the meter board at the same size. (A) The overlays for 35-mm at 7 m and for 50-mm at 10 m show different sizes and locations of items. A similar situation occurs with B. (C) All three overlaid shows a striking similarity to figure 3 because distance from camera to meter board is critical and focal length is not, as will be shown in figures 6 and 7.

Figure 6—Effects of change in camera focal length of 35-mm, 50-mm, and 70-mm, at 10-m distance from camera to meter board using 50-mm at 10 m for comparison. Objects in each photograph were outlined on clear plastic overlays and were adjusted in size to the 50-mm at 10 m from the meter board as follows: (A) 50-mm was measured at 23.0 mm for 100 percent, solid outline; (B) 35-mm focal length was 17.0 mm, enlarged to 135 percent, outlined in dots; and (C) 70-mm was 30.0 mm, reduced to 77 percent, outlined in dashes. They are compared in figure 7.

Figure 7—Object outlines for three camera focal lengths taken at 10 m from the meter board shown in figure 6. (A) Overlaying 35-mm and 50-mm shows almost no difference in object size or location. (B) Similarly, overlaying 50-mm and 70-mm shows little difference. (C) When all three are overlaid, there is almost no difference in object size or location. Camera focal length may differ without affecting analysis of photographic items when images are adjusted to a common size. A major disadvantage of using various focal lengths is the loss of background coverage in each photograph (shown in fig. 6, B and C). Comparison with figures 3 and 5 clearly demonstrates that distance from camera to meter board must remain the same.

Open to view page 18.

Figure 8—Effects of camera height aboveground on size and location of outlined objects. (A) Height of 1.4 m (4.5 ft, breast height) outlined in solid lines, is compared with (B) eye level of 1.8 m (5.8 ft) outlined in dots. The difference of 4 dm (16 in) is shown in figure 10A.

Figure 9—Effects of horizontal offset of the camera 4 dm (16 in) from center. (A) Center position is outlined in solid lines and (B) camera position to the right is outlined in dots. Difference in object size and location is shown in figure 10B.

Figure 10—Effects of altering camera position by 4 dm (16 in) vertically and horizontally on size and location of outlined objects in figures 8 and 9. The reference position is 1.4 m (4.5 ft) centered over the camera location fencepost and outlined in solid lines. (A) Vertical movement of camera position, outlined in dots, to 1.8 m results in no change in object size but significant change in location on the photograph. (B) Horizontal movement of 4 dm (16 in) to the right, outlined in dots, results in no change in object size but significant change in position with the shift in a different direction from A. Position of the camera over the camera location fencepost affects location of objects but not size of objects.

Effects of camera position on object size and location are illustrated in figures 8 through 10. The photographs in figures 8 and 9 do not look different because 4-dm movement of the camera is difficult to detect. Figure 10, however, illustrates how much movement of objects occurs with only 4 dm (16 in) of change in camera position up or sideways. Although there is substantial change in object position, there is no change in size because the distance from camera to meter board was the same. Camera position is critical if location of objects is an objective of photographic monitoring; it is not critical if change in size of object is the objective.

Few restrictions and many opportunities exist in camera selection. The objective of photo monitoring suggests the appropriate style of camera and economics dictate the sophistication.

Filing System

A filing system must be developed for repeat photography. Place each photo study in a folder complete with purposes for the monitoring, site descriptions, notes, maps, color slides, and black-and-white prints with negatives or digital memory cards with prints (Johnson 1991, Nader and others 1995). The purpose of the file is to contain everything that other people will need for rephotography. Appendix D covers filing systems in detail.

Special note—It cannot be overemphasized to label and date all slides, black-and-white and color photographs, and the negatives as they are processed. Date and study location should be recorded on slides and negatives or digital memory cards by use of photo identification forms placed in the picture view at time of photography. Too often, negatives cannot be positively identified with their prints or date of photograph. I have found this a particular problem with negatives over 5 years old that document gradual change in conditions.

With these common characteristics in mind, two kinds of photo monitoring will be discussed: comparison photos and repeat photos.

Comparison Photo Monitoring

Comparison photo monitoring means comparing on-the-ground circumstances to a set of photographs depicting various known conditions and assigning a value or rating to the field situation. This deals primarily with effectiveness monitoring and asking the question, “Did we do what we said we would?” Three examples are illustrated: (1) appraisal of fuel loading, (2) estimation of herbage utilization, and (3) monitoring of public concern.

Forest Residue Estimation

An example of comparison photo monitoring is appraisal of fuel loading (fig. 11). Maxwell and Ward produced photo series for quantifying forest residues in the coastal Douglas-fir—hemlock type (*Pseudotsuga menziesii* (Mirb.) Franco-*Tsuga heterophylla* (Raf. Sarg.) (1976a), ponderosa pine type (*Pinus ponderosa* P. & C. Lawson) (1976b), Sierra mixed conifer type (*Abies* spp.) (1979), and natural forest residues in several Pacific Northwest forest types (1980b). Other examples are Koski and Fischer (1979) using photo series for appraising thinning slash in northern Idaho, Wade and others' (1993) photo series for estimating posthurricane residue in southern pine, and Ottmar and others' (1990) sophisticated stereophoto series for quantifying forest residues in the Willamette National Forest in Oregon.

Maxwell and Ward (1980a) and Fischer (1981) present detailed instructions for developing photo series for forest residues. Their procedures were very similar except that Fischer placed the size control marker 20 ft (6 m) from the camera and Maxwell and Ward placed it 30 ft (9 m). Color was preferred by both to enhance recognition of dry and green fuel. The procedure of Maxwell and Ward follows:

1. Find very high and very low fuel loadings in the proposed forest type and size class, and then intermediate loadings. A forest type is the dominant tree species, and size class is the diameter at breast height (dbh) of the stand; for example, Douglas-fir pole size 5 to 9 in (12 to 22 cm) dbh. Their publications showed three to five different fuel loadings per forest type and size class.
2. Select slightly concave topography so that residue within 180 ft (54.5 m), a desired sampling distance, is visible.
3. Take photographs on overcast days because bright sunlight streaming through canopies creates sharp contrasts (see app. E).
4. Use a quality 35-mm camera with 50-mm lens.
5. Take the photograph in landscape format (long dimension of the photo will be horizontal.)
6. Use a reasonably fast, fine-grained color film (for example, Kodachrome 64).

1-DF-4-PC

LOADING			OTHER MEASUREMENTS	
Size class (inches)	Weight (tons/acre)	Volume (ft ³ /acre)		
0.25-1.0	1.1	61	Average residue depth (feet)	<u>0.1</u>
1.1-3.0	2.3	143	Ground area covered by residue 1/4-inch diameter and larger (percent)	<u>40</u>
3.1-9.0	2.3	174	Average duff and litter depth (inches)	<u>0.7</u>

Slash treatment <u>Machine piled & burned</u>			Slash treatment	
Period since cut or treatment (months)	<u>12</u>			

Figure 11—Fuel loading comparison photograph from Maxwell and Ward (1976a, p. 32), originally produced in color. Conditions in the field are compared to a series of photographs to estimate fuel loading. This is one of a nine-report series showing residue after commercial thinning in Douglas-fir—western hemlock, size class 9 to 20 in dbh. The data table lists fuel loading weight and volume by size class, residue depth, percentage of ground cover by residue, average duff and litter depth, sound residue larger than 3.1 in by species, rotted residue larger than 3.1 in, harvest and precommercial thinning data, and the USDA Forest Service fuel rating.

7. Shoot between f-8 and f-16 for a long depth of field.
8. Always use a tripod because low light under tree canopies may require exposures below $1/30^{\text{th}}$ of a second.
9. Use the standard national field system marker placed 30 ft (9 m) from the camera; it is a pole 6 ft (1.8 m) tall with a 1-ft² (3 by 3 dm) marker at the top and alternate foot distances painted black and white (fig. 11).
10. Take a minimum of three exposures so that all fuel loadings from different locations can be presented in the same color mode.
11. To sample fuel loading, establish five base lines radiating from the camera and equidistant apart, with five sample points on each line in view of the camera. Sample the down material from each of the 25 sample points.
12. Sample standing live and dead material from six sample points distributed over the 25 fuel loading points.
13. Compute down fuels, standing fuel (live and dead trees, shrubs, grasses, and forbs) by size class, anticipated rate of spread, and flame length under selected moisture content and wind speed.

Maxwell and Ward's format shows a color picture of fuel loading with all data contained in that picture as computed by their instructions (fig. 11). The product is a pocket-sized booklet, about 5 by 9 in (12 by 22 cm), listing the forest type, such as west-side Douglas-fir or east-side pine associated, size class of the forest type, and within each forest type and size class, three to five fuel loadings.

To use their system, a person goes to the field, identifies the forest type and size class, then turns to appropriate photographs in the booklet and compares the fuel loading at the site with pictures in the booklet. The fuel loading is then estimated by comparing the existing conditions to those described for the photograph most nearly approximating field conditions. Jensen and others (1999) applied the concept for estimating fuel loading to a fire hazard to do a watershed analysis for the parks department of British Columbia.

Herbage Utilization

Another comparison photo monitoring system deals with utilization of grasses and forbs by livestock. Schmutz (1971) and Schmutz and others (1963) pioneered a series of photographs for grasses in the Southwest. Kinney and Clary (1994) developed a series depicting various kinds of utilization on riparian graminoids (fig. 12). On a single page, the latter depict six degrees of utilization: 0, 10, 30, 50, 70, and 90 percent. To use their guide, the species in question must be identified, its stubble height determined, and the height compared to photographs in the guide to estimate the percentage of utilization.

Kinney and Clary's procedure for developing a guide is rather simple and straightforward, as follows:

1. A height-weight curve was developed for each species to be photographed. A height-weight curve is the relation of the percentage of total height of the plant with seed heads to percentage of utilization. For example, a plant 5 dm tall might have 10 percent of its weight in the top 20 percent of its height (fig. 12). Thus, a plant 80 percent as tall as an ungrazed plant would represent 10-percent utilization.
2. A plant with seed heads of the desired species is selected, vegetation removed from around that individual, and a black backdrop placed behind the plant (fig. 12).
3. The plant is photographed in its full stature. Then it is clipped at heights that represent 10, 30, 50, 70, and 90 percent utilization. At each clipping, the plant is rephotographed.
4. These six photographs are then assembled onto a single page and accompanied with a height-weight graph showing the relation between plant height and percentage of utilization (fig. 12).

Guenther (1998), working in annual grass rangeland in California, developed a photo-monitoring guide dealing with residual dry matter. He used a Robel pole² (Robel and others 1970) photographed from 10 and 20 ft. Eight photographs depict increments of annual grass biomass from over 1,000 lb/acre to less than 125 lb/acre. The Robel pole is supplemented with a 0.96-ft² hoop placed at its base with four golf balls to help appraise grass density.

His procedure is to place the pole and take a photograph. Then the vegetation is clipped within the 0.96-ft² hoop to document the herbage production.

² The Robel pole is discussed in appendix A.

Figure 12—Sedge utilization comparison from Kinney and Cleary (1994, p. 7) for water sedge. Stubble height is shown for six levels of utilization. The photograph is compared to sedge utilization found in the field to appraise the amount of use.

Figure 13—Comparison photographs of smoke from a pulpwood mill along the Columbia River taken from a turnout on Interstate 84: (A) 35-mm focal length simulating 20 mi distant, (B) 70-mm simulating 10 mi distant, and (C) 140-mm simulating 5 mi distant. Similar sets of photographs were used by Magill (1990), Benson (1983), and Ribe (1999) to appraise viewer's reactions to landscape scenes.

Monitoring Public Concern

Monitoring of public concern for landscape quality also uses a comparison photographic technique as discussed by Benson (1983), Magill (1990), and Ribe (1999). Their objectives were to test public awareness and concern for various landscape items, particularly effects of logging. Magill (1990) used a set of three to five photographs of the same landscape viewed at different distances (fig. 13). These were shown to people and their reaction or concern about the view documented. He tried to develop a threshold definition of various landscape features. The technique was as follows:

1. A landscape feature was selected as viewed from a suitable vantage point, such as a road or viewpoint.
2. This landscape was photographed with a 35-mm camera using color film and a zoom lens. Pictures were taken at 50, 70, 100, and 150 mm (fig. 13). This was done to simulate different distances from the landscape object, for example, 4.8, 3.2, 2.1, and 1.6 mi for each focal length, respectively.
3. No effort was made to select good visibility or particular weather conditions (fig. 13).

Benson (1983) discusses scenic beauty estimation and visual quality objective analysis through methods similar to those of Magill (1990). He also uses comparison photos to rate elk habitat characteristics and recreational impacts as part of forest planning. Ribe (1999) used photographs to test public response to 15-percent retention of green trees in clearcuts as a research method for appraising acceptance of alternatives in the Northwest Forest Plan.

Repeat Photography

As the name implies, repeat photography means retaking photographs from the same spot and of the same subject several times. To be effective, most repeat photography requires precise replacement of the camera and composition of the subject, be it a sample plot, view of a particular subject such as a streambank, or rephotographing a distant landscape.

Repeat photography is used for many purposes and, thus, can take on many different forms. It may be landscape rephotography covering 50 to more than 100 years of change (Skovlin and Thomas 1995); documenting animal activity at a specific site, such as ospreys (*Pandion haliaetus*) rearing young (Kristen and others 1996) or livestock distribution in a meadow (Kinney and Clary 1998); assessing air quality (Fox and others 1987); sampling change in vegetation using both general and closeup views (Hall 1976, Nader and others 1995); and appraising effects of management such as livestock utilization or logging (Gary and Currie 1977, Kay 1999, Kay and others 1999, Smith and Arno 1999). Hart and Laycock (1996) and Rogers and others (1984) present bibliographies on repeat photography. In this paper, a riparian setting, Pole Camp in eastern Oregon, will be used to illustrate various aspects of repeat photography.

Three things must be done for repeat photography to be successful: (1) map the site and the system layout, (2) document the system, and (3) permanently mark camera locations and photo points.

Figure 14—USDA Forest Service Ranger District map showing locations of the Button Meadow, Pole Camp, and Lower Emigrant riparian study sites in northeastern Oregon. Road numbers, mileage from road junctions, and directions to the witness sites (a tree or fencepost with an orange tag identifying the monitoring area) are given in the study writeup.

Maps of Location and Monitoring Layout

Maps are essential for relocating and rephotographing topics as discussed by Bauer and Burton (1993), Borman (1995), Governor's Watershed Enhancement Board (1993), Hall (1976), Nader and others (1995), National Park Service (1992), USDA Forest Service (1982), and USDI Bureau of Land Management (1996). Two maps are important:

1. Map of the monitoring site location so that those other than the installers can find it. Figure 14, a USDA Forest Service ranger district map, identifies the road on which the site is located. Establish a witness marker along the road by placing an orange tag on a tree or fencepost. Inscribe on the tag the identity of the monitoring site.
2. A map of the photo monitoring system layout so that others can duplicate the original photography (fig. 15). From the witness marker identified on the general map, record directions and measured distances to each camera location and photo point (fig. 15). Measure on the ground; do not attempt conversion to horizontal distance.

The emphasis on *others* (other people) refers to a problem discovered by many (Borman 1995; Gruel 1980, 1983; Johnson 1984; Magill 1989; Nader and others 1995; Parker and Harris 1959; Phillips and Shantz 1963; Progulske and Sowel 1974; Puchbauer and Carrol 1993; Reppert and Francis 1973; Strickler and Hall 1980; USDA Forest Service 1982; USDI Bureau of Land Management 1996).

Figure 15—Study layout of the Pole Camp riparian site. Notice that all compass headings are shown as magnetic (M) to reduce confusion with the 21-degree deviation from true north in the Pacific Northwest. When distance is shown with a decimal point, it indicates a measured rather than a paced distance. Notice the two photo points from camera location 1—dry and wet. The boxed map is shown later in figure 27, which details location of the instream photo point.

Compass deviation is one item of particular importance in laying out the site map and relocating sites for repeat photography. In the Pacific Northwest, deviation is about 21 degrees east. The problem is, What does this mean? Does one add or subtract 21 degrees from the magnetic compass heading? Most people traveling by water, air, or land use magnetic headings for their direction; land survey, on the other hand, uses true direction. When providing direction on any map, specify true or magnetic. Notice in figure 15 that direction is listed first and distance second to provide easily followed instructions: You have to know what direction you are going before you can start moving.

Documentation of the Photo System

Each repeat-photography monitoring system must be documented in writing (in other words, a protocol for operation is created). It should include the following items:

1. The original size and focal length of camera such as a 35-mm camera with 50-mm lens or a 2- by 2-in (50- by 50-mm) square format camera with 70-mm lens.
2. The film to be used: speed and type of film such as Kodachrome 64 versus Elite Chrome (Ektachrome) 200, color or black and white negative film. Using both may require two different cameras or one camera with two backs. Digital cameras do not use film.

3. Definition of methods for repeatability of photographs. Specify how to aim the camera to repeat the field of view; for example, "site on the 1M of a meter board." The field of view must be held constant so changes in the subject matter, such as stream stability, vegetation change, or management activities, can be clearly documented.
4. Time of day, season of year, air quality for landscape rephotography, and lighting conditions, such as overcast sky to reduce shadows or backlighting to highlight vegetation (app. E).
5. A list of all equipment required.
6. Instructions for using mechanical or electronic aids for rephotography.

Permanent Marking

Witness sites, camera locations, and photo points or transects must be permanently marked for efficient photo monitoring. Steel stakes or fenceposts can be used. Each has advantages and disadvantages:

1. Steel stakes are difficult to find if vegetation overtops them.
2. Steel stakes protruding above the ground may be stepped on by animals or people, or run over by vehicles causing foot or tire damage. Stakes can be driven flush with the ground but then will require a metal detector to be relocated (White's Electronics, Inc. 1996).
3. Fenceposts are clearly visible and thus subject to theft.
4. Cheap fenceposts made of stamped steel are useful and durable (including against theft) when purchased in 5-ft (1.5-m) lengths and pounded 2 ft (0.6 m) into the ground. The 3 ft (0.8 m) above the ground is easily seen, and the flimsy construction deters theft because the stamped steel posts are as difficult to remove as strong T-bar posts.
5. Any fencepost aboveground is subject to destruction by equipment when an area is disturbed. When disturbance monitoring is contemplated, stakes driven flush with the ground are appropriate. Most inexpensive metal detectors will locate a 3/8-in (1-cm) diameter steel stake driven flush with the ground within a radius of 12 in (3 dm) (White's Electronics, Inc. 1996).

With this background, three kinds of repeat photography will be discussed: (1) landscape photography, (2) remote photo monitoring, and (3) site-specific monitoring.

Landscape Photography

Repeat landscape photography seems to have been devised by Professor S. Finsterwalder, who photographed and mapped glacial changes in the eastern Alps starting in 1888 (Hattersley-Smith 1966). In the United States, after the Civil War, photographers were invited to participate in exploring the Western United States. Some of these historical landscape pictures have been rephotographed 100 or more years later; for example, Progulske and Sowel (1974) rephotographed the area of Colonel Custer's 1874 exploration of the Black Hills to show changes in 100 years,

Figure 16—Relocation of historical photographs showing a view (1992) by Skovlin and Thomas (1995, p. 22-23) of Branson Creek, Wallowa County, Oregon, originally photographed in 1914 (top picture). The letter "A" identifies centerline orientation. Once the photographer was centered as on the original photograph, objects on the edges of the picture, such as "B" and "C", were chosen to refine location of the original camera. The photographer has to move forward or back until the angles of "B" and "C" are similar to the original photograph. Slight differences in orientation lines between 1914 and 1992 suggest the camera in 1992 was a few yards left of the original location. The usefulness of black-and-white photographs is illustrated here by triangulation lines placed directly on the picture.

and Skovlin and Thomas (1995) illustrated changes over 70 to 90 years in eastern Oregon (fig. 16). Landscape photography of small areas (10 to 100 ha) is discussed later and will be shown in figures 26 and 38. Appendix E illustrates some photographic techniques.

Johnson (1984), whose purpose was to evaluate change in sagebrush (*Artemisia* spp.) over 100 years or more, retok pictures taken by William H. Jackson during the 1860s to 1870s as part of the Hayden Expedition in Wyoming. Johnson concluded

that sagebrush is highly site-specific, some changes have occurred but they differ among sites, and there has been no major shift in sagebrush distribution, although densities have changed. He felt the landscape today is a fair representation of the 1870s.

Phillips and Shantz (1963), who compared photographs taken by Dr. Shantz 50 to 60 years previously, report on another historical photo series of vegetation changes in the northern Great Plains. Dr. Shantz also photographed in eastern Colorado in 1904. Many of the locations for his pictures were rephotographed in 1986 after 82 years (McGinnies and others 1991).

Branson (1985), Gary and Currie (1977), Gruell (1980, 1983), Johnson (1987), Puchbauer and Carroll (1993), Rogers (1982), and Veblen and Lorenz (1991) discuss additional landscape rephotography.

Purpose

Purposes other than historical documentation have prompted long-term retaking of landscape photographs. Long-term, in this context, refers to retaking photographs taken by another person, usually more than 20 years previously. Some have evaluated effects of livestock grazing and change in western rangelands (Branson 1985; Chaney and others 1991; Johnson 1984, 1987; McGinnies and others 1991; Phillips and Shantz 1963, Skovlin and Thomas 1995).

Changes in rangeland vegetation from 1902 to 1988 were documented by Medina (1996) in his history of the Santa Rita Experimental Range in southern Arizona. Fifty years of secondary succession under sheep grazing in green fescue (*Festuca viridula* Vasey) grasslands were rephotographed in the Wallowa Mountains (Reid and others 1991), and effects of revegetation in green fescue grasslands depleted by sheep grazing in the Wallowa Mountains were shown by Strickler and Hall (1980). They documented Dr. Arthur Samson's pioneer range work in rehabilitation, which helped to formulate the first textbook on range management.

Other uses for long-term landscape photography have been to appraise the historical effects of fire on wildlife habitat in the Bridger-Teton National Forest, Wyoming (Gruell 1980, 1983); forest health concerns in the Boise National Forest, Idaho (Puchbauer and Carroll 1993), which used photography from as early as 1870; changes in wildlife habitat in north Yellowstone (Houston 1982); causes for mule deer (*Odocoileus hemionus* Zimm) population eruptions in the intermountain West (Gruell 1986); long-term successional changes in Blue Mountain ecosystems (Skovlin and Thomas 1995) as it affects forest health, range condition, and wildlife habitat; and to illustrate change in research natural areas (Herring and Greene 1997).

Considerations in long-term repeat landscape photography include three important factors:

1. Relocating photographs done 50 to 100 years previously.
2. Duplicating photographs taken by cameras that are no longer manufactured or available.
3. Dealing with photographic conditions such as season, weather, light, and air quality.

Relocation

Most authors say that finding the camera location was their most difficult problem. Without precise camera relocation, duplicating the scene photographed by original cameras and duplicating weather conditions were unimportant (Gruell 1980, 1983; Hart and Laycock 1996; Johnson 1984; Phillips and Shantz 1963; Progulske and Sowel 1974; Puchbauer and Carroll 1993; Skovlin and Thomas 1995).

Johnson (1984) notes that each: "...photosite was relocated over a 12 year period through time-consuming search in the field aided by knowledge of the countryside and comparison of expedition maps and reports with modern references." He was referring to the Hayden Expedition. He also says that: "...the exact photo point was relocated by detailed inspection of photo features" (see fig. 16 and app. E).

A summary follows of comments by authors who have had to relocate landscape photography camera locations after 50 or more intervening years:

1. Study the travel log books, trail routes, and other descriptions of travel, not overlooking the slow rate of movement by horses and wagons, to locate a geographical area in which the old photograph might have been taken (Progulske and Sowel 1974).
2. Show the old photographs and descriptions to local residents for their ideas about location. In many cases, original photographers did not know local names of buttes; however, shape of the buttes and landforms are clues current residents can use to suggest camera locations (Progulske and Sowel 1974). If no travel logs are available, study of historic travel routes and railroads can provide clues as to where the photographers traveled and where they might have photographed (Phillips and Shantz 1963).
3. Identify unique landscape features such as hills, drainage ways, and their inter-relationships. Phillips (in Phillips and Shantz 1963) comments that Dr. Shantz always seemed to find a prominent landmark to include in his photos, even on the Great Plains, which greatly aided in relocation. Many of Shantz's photos were taken from the first railroads into an area where he would take photographs from a siding, town, or coaling station that could be readily relocated.
4. Orient the camera location by lining up near and distant objects in a triangulation system (fig. 16). For example, Progulske and Sowel (1974) point out that mountain profiles, abundance of rocks, thickness of soil, escarpments, and stream configuration were used. A search then can be made for rocks or dead trees, which lead to the target camera location. As Puchbauer and Carroll (1993) note, objects in the original photo often are overlooked during first examination; they suggest using a hand lens to locate subtle objects, such as old monarch trees (or their remains), on black-and-white photos.³

³ In my experience, black-and-white prints are superior to color slides in relocation because prints can be easily examined by hand lens, and triangulation lines, shown in fig. 16, may be placed directly on the photograph.

5. Problems with relocation:

- A. Historic travel routes, roads, or railroads may have been obliterated by modern activities, thereby making identification of camera locations difficult.
- B. Intervention by other objects is one of the most common problems encountered. These objects can be trees, buildings, or other obstructions to the view from the original camera location.
- C. No clear, identifiable landscape feature by which to locate even the general area of a photograph.

Considerations

Camera—The original cameras and films cannot be duplicated by equipment available today in nearly all cases of photography before 1930. Duplication of the original scene, therefore, requires matching negative size with focal length to replicate the original photographs as nearly as possible. For example a 4- by 5-in press camera with 128-mm lens is roughly similar to a 35-mm camera with 50-mm lens. Most authors of historic landscape rephotography comment on this situation and recommend solutions. Rogers and others (1983) deal specifically with this problem and demonstrate that camera format is not critical; camera location and distance to featured objects are the critical factors. They discuss adjustment of print size to original prints and some problems with loss of items on the periphery of photographs; for example, some detail is lost when using a 35-mm camera format (a 2-to-3 ratio) to duplicate a 4- by 5-in format (a 2-to-2.5 ratio).

Film—Film, of course, also is different; one would hardly expect to use a wet plate glass negative in today's world. And even if an early camera is still in working condition, compatible films no longer are made.

Season and weather—The season and weather (lighting conditions, time of day, and air quality) are a third important consideration in long-term landscape rephotography. Many authors note that not all the original photographs could be used because of poor quality due to air conditions, deterioration, processing, or inadequate photographic technique. When a photo site was found, Johnson (1984) points out that "subsequently, one or more visits were made to the site to duplicate as closely as possible the light, time of day, and date of originals."

These problems and conditions lead to rejection of many photographed landscapes as subjects for rephotography (Gruell 1980, 1983; Johnson 1984; Phillips and Shantz 1963; Progulske and Sowel 1974; Puchbauer and Carroll 1993; Skovlin and Thomas 1995).

Panoramic cameras—Panoramic cameras also have been used in landscape photography (Arnst 1985, Hanemann 1989). Hanemann describes the Osborn photo-recording transit, which is a unique camera once built in Portland, Oregon. The lens rotates through an arc of 120 degrees and focuses through a narrow slit onto a negative held in a semicircular position. This camera was used to rephotograph some of the scenes taken by Arnst (1985) in the Cascade Range of Oregon.

Figure 17—Panoramic photography using the rotating Hulcherama® Model 120 camera. The camera has no shutter. Instead, light is admitted through a vertical slit shown by the solid white bar (1) on the right in C. Amount of light is governed by a lens f-stop and by speed of camera rotation. (A) The camera begins its 360-degree rotation with the white line in C, then (B) continues past 360 degrees a few degrees to overlap the image. (C) Once started, the camera must continue to rotate at a specified speed. Should it be stopped, a fuzzy white strip will occur as shown by the white line (2) left of line (1) in C. A meter board has been used as a reference for the start of the rotation.

Today, panoramic cameras are built such that the camera itself rotates on a 360-degree arc while the film moves at the same rate of speed. The image passes through the lens and is constrained by a thin slit. The film rotates past the thin slit. An example is the Hulcherama[®] model 120 camera (Hulcher, n.d.; fig. 17).

Panoramic cameras have a singularly important requirement: they must be very accurately leveled so that rotation of the camera will photograph a constant horizon and this photograph can be retaken at a later date. Modern cameras can use both color and black-and-white film, commonly in 120 size, 12-exposure rolls. Exposure is determined by f-stop, slit width, and speed of camera rotation (Hulcher, n.d.).

Figure 18 illustrates problems using the meter board to orient general photographs instead of keeping a panoramic camera level. Camera location 1 at Pole Camp was chosen as the center of a 360-degree panoramic view of the area. Camera format was a 50-mm lens on a 35-mm camera body. The meter board was placed 10 m from the camera. For each successive photo, it was moved 8 m in a 10-m radius around the camera. On a flat flood plain, a meter board could be used to focus and orient the camera. However, camera orientation on the meter board in the stream of figure 18B lowered the view 1.3 m at the board, thereby causing displacement of the photos. Arrows point to a rock at top and a shrub in the center for orientation. An ideal panoramic view would have the camera level in all views to show changes in topography; thus the meter board would be lower in figure 18B and unusable for photo orientation.

Jensen and others (1999) used a camera rotated on a tripod similar to figure 17. In a test of observer variability, they found that 72 percent of the repeat photographs did not attain 20 percent overlap with originals. The causes were swapping cameras during rotation (to change film), thus causing misalignment of the view; inconsistent placement of the photo identification card, which should be placed at the same distance and location in the photo; and significant inconsistencies in exposure, which rendered some photos unacceptable for comparison because sun angle changed during 360 degrees of view.

Figure 18—Two photographs of a 360-degree panoramic view of Pole Camp from camera location 1. The camera was focused on the “1M” of the meter board, similar to topic photographs, as a means for exact reorientation of subsequent pictures. As a result, view **B** is significantly displaced because the meter board is about 1.3 m lower than in view **A**. Overlap items are shown at arrows that cross from **A** to **B**. The number (2) identifies camera location 2. Above the (2) is the lodgepole pine witness stump. Figure 15 is a map of this site.

Figure 19—Mechanically triggered camera system used by Bull and others (1992) to monitor presence of marten (*Martes americana* Turton). Bait (arrow, lower right) was suspended on the tree to the right under a cover as one modification for winter operation. Camera was a 110 size with flashcube.

Remote Photo Monitoring

Remote photo monitoring uses unattended camera or video systems. Repeat photos are taken of a specific view, which may be a landscape (Fox and others 1987) or a specific activity such as a nest of ospreys (*Pandion haliaetus* Linn.) (Kristen and others 1996). Zielinski and Kucera (1995) deal with photo detection of animal presence in detail (fig. 19). Because remote photo monitoring is a topic unto itself, only a few examples will be presented.

Time-lapse systems have been described by Bryant,^{4 5} Bull and Meslow (1988), Fox and others (1987), Kinney and Clary (1998), Kristen and others (1996), and Temple (1972). They all used timing systems to trigger the camera at specified intervals ranging from fractions of a second to several hours. Movie cameras, 35-mm cameras, and video cameras were used. Bull and Meslow (1988) monitored pileated woodpecker (*Dryocopus pileatus* Linn.) chick feeding with a super 8-mm camera set to expose a frame every 8 to 12 seconds (Temple 1972).

Bryant (see footnote 4) used a time-lapse super 8-mm movie camera (Temple 1972) to monitor winter ice floods on Meadow Creek in eastern Oregon. The location was a research study site testing various livestock grazing effects on riparian ecosystems. The 45-minute flood lasted about 4 minutes at standard speed in a movie projector. Super 8-mm movie cameras have been replaced by camcorders.

⁴ Personal communication. 1990. Larry D. Bryant, wildlife biologist, on Meadow Creek flood. USDA Forest Service, Pacific Northwest Research Station, 1401 Gekeler Lane, La Grande, OR 97850-3368.

⁵ Personal communication. 1990. Larry D. Bryant, wildlife biologist, on remote video camera. USDA Forest Service, Pacific Northwest Research Station, 1401 Gekeler Lane, La Grande, OR 97850-3368.

In another study (see footnote 5), Bryant used time-lapse remote video to document livestock use of riparian areas. He found that video "film" is less expensive than camera film, instant viewing and transmission were advantages, and cost of camcorders and deterioration of video film were disadvantages.

Kinney and Clary (1998) monitored livestock distribution patterns over several grazing seasons in meadows through repeat 35-mm camera photography. The camera took a picture every 20 minutes during daylight hours during a 15- to 20-day grazing period on three meadows over 2 to 4 years. Dry graminoid locations were preferred even though forage production was not the highest. They emphasized several things: The sun must be behind the camera for all exposures. The camera must be set to expose for the desired kind of vegetation; for example, on grass and not on the surrounding evergreen forest. And, animals are curious and often affect the camera location by pushing on it, which modifies the camera aim or destroys the installation.

Fox and others (1987) discussed monitoring of air quality with a 35-mm camera. Their equipment was a 35-mm camera body with a 135-mm lens, automatic winder, automatic exposure designed to be on only during the exposure (not continuously), an ultraviolet filter, a data back capable of imprinting the date and time, and a battery-powered programmable timer capable of triggering the camera at least three times per day in a housing for the complete system capable of standing alone and operating in temperatures from -34 to $+54$ °C while being unattended for at least 10 days. Their criteria state that the site must contain at least one horizon-visibility target with as many of these characteristics as possible: (1) large, (2) identifiable on a topographic map, (3) dark vegetation (such as conifers), (4) 32 to 80 km in distance, (5) two or three targets at various distances, (6) camera and target at about the same elevation, (7) target centered in the camera viewfinder, (8) site path not affected by local sources of air pollution, (9) target as free of snow in winter as possible for contrast, (10) exceptionally bright or dark foreground objects avoided, and (11) camera oriented to avoid sun on the lens for pictures taken any time during the day. They provide a diagram and a system for evaluating film by using microdensitometric analysis of color slides.

Kristen and others (1996) monitored osprey nest activity over a season by using a video camera set to expose one frame every six-tenths to one second. The images were then transmitted by a directional antenna to a receiving station up to 8 km distant and viewed on a monitor. The lapse in time could be adjusted at the monitor receiving station. A deep cycle battery supplemented by a solar panel supplied the power to the system.

Figure 20—Pole Camp “wet” sample location showing three dates of the same year. June 15 is before scheduled grazing, August 1 is at change in rotation pastures, and October 1 is after grazing. This pasture was rested from June 15 to August 1. October 1 illustrates the degree of livestock use of Kentucky bluegrass at the meter board, aquatic sedge behind the board, and willows in the distance.

Site-Specific Repeat Photography

Site-specific means that a camera location and photo point or transect are permanently marked to document a specific topic on a limited tract of ground (not a landscape view) (Jensen and others 1999, Smith and Arno 1999). Directions and measured distances from witness site to camera locations and from camera to photo points or transects are required for precise relocation. For example, figure 20 is Pole Camp photo point "wet" (the wet meadow view). Topics were animal affects on willow shrubs (*Salix* spp.) and herbaceous stubble height remaining after grazing along the stream and adjacent meadow. A different kind of topic, planned disturbance and plant community development, is illustrated in figure 21.

Site-specific repeat photography may be divided into two kinds: topic and transect systems.

Topic Photographs

Topic photographs are shown in figures 20, 21, 22, and 23, where specific topics were monitored. This system uses a general photograph and may be supplemented by closeup photos of the meter board, a single plot frame (fig. 24), or overhead tree cover (fig. 25). Cole (1993) points out some limitations of topic photography when documenting damage to soils and vegetation from wilderness recreation. He indicates that measuring change from the photographs was difficult.

Transect identification using topic photography is used in the three-step method (Parker 1954, Parker and Harris 1959). In this method, Reppert and Francis (1973) could appraise species identification and their change in density and could verify correct replacement of the transect.

In British Columbia, Jensen and others (1999) applied topic photography to monitor recreational impacts, fuel loading, riparian vegetation and stream channels, disturbance recovery, and quantitative measurements of change in soil and vegetation. In an appraisal of observer variability, they found that a topic photopoint system could attain 80 to 100 percent overlap 95 times out of 100 (95-percent probability).

French and Mitchell (1983) used the single-topic approach to photograph change in shrubby vegetation in southern Idaho over 21 years. Pond (1971) evaluated an increase in chaparral (*Quercus* spp., *Ceanothus* spp., *Rhus* spp., *Arctostaphylos* spp.) for 47 years in an enclosure erected in 1920. Sharp and others (1990) show 40 years of change in a shadscale (*Atriplex confertifolia* (Torr. and Frem.) S. Wats.) stand in Idaho and correlate it with growing conditions to appraise effects of local weather on species dominance. In another study, Sharp and others (1992) document crested wheatgrass (*Agropyron desertorum* (Fisch. Ex Link) J. A. Schultes) production over 35 years and correlate it with growing conditions. Medina (1996) photo documented vegetation changes in the Santa Rita Experimental Range in southern Arizona at five locations: Burroweed (*Haplopappus tenuisectus*) increased and decreased with precipitation; jumping cholla (*Opuntia fulgida*) was absent in 1902, increased by the 1940s, then decreased; velvet mesquite (*Prosopis juliflora*) increased dramatically on mesic uplands but not on clayey, stony soils; and Lehman lovegrass (*Eragrostis lehmanniana*) increased and displaced many native species.

Figure 21—Aponderosa pine stand with pinegrass ground vegetation showing conditions after logging: undisturbed in 1981, after the first partial overstory removal in 1982, and in 1998 after the second overstory removal and precommercial thinning. These views, with their dramatic differences, emphasize the need for permanent marking of both camera locations and photo points. Exact reorientation of the picture uses the “1M” of the meter board as the photographic center (see fig. 29). All photographs were taken the first week of August.

Figure 22—Photo monitoring each year at the same date (August 1) to document herbage production in a ponderosa pine stand with pinegrass. In 1979, drought occurred, which resulted in elk sedge (*Carex geyeri* Boott) dominance and only 400 lb of total herbage per acre. In 1980, lupine (*Lupinus caudatus* Kellog) was clearly important and pinegrass dominated over elk sedge with total herbage of 700 lb/acre. In 1981, Wheeler's bluegrass (*Poa nervosa* (Hook.) Vasey) was important, lupine was nearly absent, and pinegrass was common with total herbage of 750 lb, and in 1982, pinegrass was again clearly dominant without much bluegrass or lupine with total herbage about 600 lb/acre. Notice the lack of shadows under overcast skies in 1979 and 1982 compared to full sun in 1980 and 1981.

Effects on vegetation, soil, and streambanks from adjustment in livestock management are shown by Anderson and others (1990), Chaney and others (1991), Elmore and Beschta (1987), and Skovlin (1991). In Elk Creek, Oregon, a pair of repeat topic photographs was used to show riparian improvement (USDA Forest Service 1993).

Gary and Curry (1977) document changes in soil condition and erosion with a 40-year photographic record of plant recovery on an abused ponderosa pine watershed in Colorado. Skovlin (1991) shows changes in soil and vegetation on a forest zone bunchgrass type with a series of 1939, 1949, and 1989 photos that follow a shift in cattle grazing from season-long to deferred rotation.

Fire effects were followed by Lyon (1984), who presents 21 years of postfire change at the Sleeping Child burn, and Stickney (1986), who presents a similar series of photographs on succession for the first decade after the Sundance fire, both in northern Idaho. In another case, Lyon (1971) documented vegetation development

Figure 23—Streambank monitoring at the Pole Camp study site. In 1981 the camera location was 3 dm from the bank at a bend in the stream. An ice flood during early spring 1982 eroded the bend of the stream, increased its meander, and destroyed the camera location. In 1982, the camera was relocated 1.3 m to the left and 1 m back from the original location. The result was (1) apparent movement of the right bank, (2) the hole indicated by an arrow shows that only a portion of the bank fell into the stream, and (3) the angle between a rock in the stream bed and the camera to meter board was changed from 44 degrees to 39 degrees demonstrating the camera relocation. This kind of change in camera location or photo point should be avoided.

Figure 24—A1-m² plot frame marked at 2-dm intervals. Plot frames are quite useful in sparse vegetation such as the Crooked River National Grassland. The decimeter marks may be used to grid the plot frame (similar to fig. 28, below) to appraise vegetation change. However, riparian areas or other dense vegetation make plot frames questionable for photography, as suggested by figure 34.

after prescribed burning of Douglas-fir in south-central Idaho for 7 years; preburn and postburn vegetation was sampled, and photo points were established and recorded annually for the 7 years. His publication shows prefire vegetation and conditions 1, 3, and 7 years after burning. Blaisdell (1953) documented effects of prescribed burning on big sagebrush-wheatgrass. He shows one general two-photo series and a closeup six-photo series of before, immediately after, and 1, 2, 6, and 12 years after the burn. Johnson (1998) shows 5 years of response to fire by grassland and forest in eastern Oregon. The National Park Service (1992) provides detailed guides for documenting fire effects on vegetation.

Fire suppression effects in ponderosa pine stands are documented by Biswell (1963), Gruell and others (1982), and Weaver (1957, 1959). Smith and Arno (1999) provide repeat photos at 13 locations for an 88-year period. Gruell and others (1982) show 10 sets of repeat photographs of changes in ponderosa pine stands after logging and fire suppression. Shinn (1980) illustrates effects of fire suppression on western juniper (*Juniperus occidentalis* Hook.) sites.

Documentation of logging effects is shown in figure 21. In 1978, conditions were an undisturbed ponderosa pine overstory with pinegrass ground vegetation (*Calamagrostis rubescens* Buckl.) in the southern Blue Mountains of Oregon. The site was entered twice for selection cutting. The 1982 photo shows stand conditions after the first selection cut, and the 1988 one shows conditions after the second selection cut and precommercial thinning. Edgerton (1983) illustrates effects of logging on bitterbrush (*Purshia tridentata* (Pursh.) DC.) under lodgepole pine (*Pinus contorta* Doug. ex Laud.).

Figure 25—Photographs taken with a fisheye lens document change in forest canopy in a study of gap creation and effects on ground vegetation in 50-m-tall Douglas-fir (Easter and Spies 1993): (A) Canopy conditions before gap creation, and (B) canopy conditions after gap creation. Photographs cover a 180-degree vertical angle.

Another use of topic photo monitoring was documentation of harvester ant (*Pogonomyrmex owyheei* Cole) colonies over 9 years in southern Idaho (Porter and Jorgenson 1988).

In forested settings, tree cover often influences ground vegetation. Brown (1962) photographed tree canopy cover over a 180-degree arc using a special camera system. More recently, Chan and others (1986) applied electronic scanning and computer techniques to analysis of fisheye photographs under 50-m-tall Douglas-fir. Figure 25 illustrates use of fisheye photographs to monitor change in forest canopy following treatment to create small gaps (Easter and Spies 1993).

Topic photography does not have a fixed protocol similar to transect systems. Any topic that can be photographed is suitable; this is a very flexible concept.

Transect Photographs

Transect photo monitoring is a specialized activity dealt with in appendix A. Briefly, a general view of the transect is supplemented by closeup photographs taken of sample plots systematically along a line (fig. 25). Discussions are available in Bonham (1989), French and Mitchell (1983), Hall (1976), Lyon (1971), Nader and others (1995), National Park Service (1992), Owens and others (1985), Pierce and Eddleman (1970, 1973), Pond (1971), Ratliff and Westfall (1973), USDI Bureau of Land Management (1996), Wein and Rencz (1976), Wells (1971), and Wimbush and others (1967).

Winkworth and others (1962) supplemented their study of five measurement methods with systematic quadrant photographs taken from a stepladder. The photos gave an excellent representation of bunchgrass canopy coverage but were difficult to measure. Measurement required a simplification of the grass canopy outline, which introduced observer variability.

Transect photo monitoring may be summarized as follows:

1. Lay out the system and document it on a sitemap with directions and measured distances to camera locations and transect start and end (fig. 15).
2. Use the specified camera and focal length. Some recommend a 35-mm camera with a 28-mm lens. The 28-mm focal length will permit photographing a 1-m² plot with the camera held at eye level. Others recommend a 35-mm camera with 50-mm lens for small plots and oblique angles for larger plots (fig. 24).
3. Take two general photographs of the transect, one from each end, that include the photo identification form.
4. Use the required plot frame, such as 0.5 by 0.5 m or 1 by 1 m, placed at specified distances along the transect with a photo identification form (fig. 24).
5. To photograph and prevent shadows, stand on the north side of the plot frame, with toes touching the plot frame; make sure the photo identification form is visible.
6. Record data and information required by the system.

Figure 26—Landscape view of the Pole Camp riparian study flood plain. One problem with these landscape views is the lack of a fixed photo orientation spot, such as the meter board used in topic photographs (figs. 1, 20, 21, 23, and 28). Rephotographing the scene requires techniques similar to those shown in figure 17.

Pole Camp

Examples of site-specific repeat photography will use Pole Camp, a riparian meadow within a forested setting north of Burns, Oregon (fig. 26). In 1975 the cattle grazing system in Emigrant Creek watershed was changed from season-long use to a three-pasture, rest-rotation system wherein one pasture is spring grazed, a second is fall grazed, and a third is rested. This grazing is rotated over the following two years so that no pasture is used during the same time each year of a 3-year cycle. The purpose was to reduce livestock impacts on the riparian area and its stream. Monitoring was designed to appraise effectiveness of changed grazing. The five questions—why, where, what, when, and how—were addressed as follows.

Monitoring questions—*Why* to monitor dealt with the effectiveness of rest-rotation cattle grazing in improving riparian ecosystem function.

Where to monitor was determined by identifying critical or key livestock grazing areas. Pole Camp is one of three locations selected (figs. 14 and 26). Figure 14 is a road map locating the three areas, and figure 15 shows the Pole Camp monitoring layout.

What to monitor dealt with selecting specific sites at Pole Camp to record stream-bank stability (fig. 23), riparian shrub (*Salix* spp.) growth in height and crown width (fig. 20), herbaceous stubble height tall enough to trap sediments (fig. 20C), and herbaceous plant community stability, deterioration, or improvement (fig. 20).

Figure 27—Triangulation location of the meter board (shown in figure 23) to document streambank erosion at Pole Camp. This map is the boxed area shown in figure 15. Any photo point or camera location in a tenuous spot should be referenced by two or more locator stakes.

When to monitor for livestock impacts was dictated by the grazing system, which required three monitoring times during the season: June 15 just before cattle grazing, August 1 as pastures were rotated, and October 1 after the grazing season ended (fig. 20). Pole Camp was used two years out of three: spring one year, fall another, and no use the third year.

How to monitor required developing a system of landscape, general, and closeup photos. A meter board in general photos is used for two closeup photos, one on each side of the board. A meter board generally was not used in the landscape pictures (fig. 26). An integral part of *how* was a map of the sampling layout (fig. 15) and any specific instructions, such as location of the instream meter board (fig. 23) shown in figure 27.

Exact Relocation

Exact relocation of photographs is one essential ingredient in site-specific photo monitoring (fig. 20). This is required if any comparison analysis of photographs is contemplated (Magill 1989, Rogers and others 1983; fig. 28 and app. A). Analysis

entails comparing or overlaying photographs so change in the subject matter, usually vegetation, can be analyzed. Analysis may be through the use of grids as shown in figure 28 (Magill 1989 and app. A) or by use of digitizing (Cunningham and others 1996).

Exact realignment of general photographs is greatly facilitated by use of a target as shown in figures 20, 21, 28, 29, and 30. A meter board is recommended to mark the topic of interest, which usually is located in the center of the photograph. Place the meter board at a distance such that it will be 25 to 33 percent of the height of the photograph. Using a 35-mm camera with 50-mm lens, 10 m from the camera will produce 25-percent meter board height (fig. 2) and 7 m will produce 33 percent (fig. 2). This 7 m also will produce a 25-percent meter board height with a 35-mm camera lens (fig. 4). Both the camera location and the meter board (photo point) are then permanently marked with fenceposts or steel stakes. The meter board is designed such that the numbers and letters can be read easily from a color slide or black-and-white photograph. Details of meter board construction are in appendix C.

A successfully used alternative employs a target board 0.5 m wide and 2.5 m tall set 10 m from the camera. The board is painted black and white alternately every 0.5 m (Van Horn and Van Horn 1996). It was designed to document riparian rehabilitation efforts in herb and shrub vegetation.

Camera Techniques

General photographs—Consistent rephotography requires a reference point to orient subsequent views. The objective is to have the view remain constant while items within the view change. A meter board serves this purpose. Figure 29 illustrates three repeat photographs of a ponderosa pine-elk sedge community that was selectively cut; figure 29A illustrates how the camera focus ring is placed over the “1M.” This accomplishes two things: (1) it provides a common orientation point for the first and subsequent photographs, and (2) it provides a locus for focusing the camera for maximum depth of field. When the meter board is placed at the topic of interest, the topic should be in sharp focus. Figure 30 illustrates effects of various camera orientations.

The meter board also provides a size control for indexing a grid. A grid can be overlaid on the photograph as suggested by Magill (1989), depicted in figure 28, and discussed in appendix A. Grid analysis entails outlining each topic of interest and counting the number of grid intersects within the outline. Figure 30D shows sloppy installation of the meter board because the board is not vertical. Vertical orientation is essential if grid analysis is contemplated. Appendix C has construction plans for a meter board that include attaching a line or pocket level to the top so that the board can be oriented vertically.

Text continues on page 54.

Figure 28—Grid intersect system used to outline and follow items with intersecting grid lines. This is Pole Camp wet (fig. 20) showing change in willow shrub profile area from 1981 to 1997 following 12 years of beaver (*Castor canadensis* Kuhl) utilization and high water tables caused by dams. In 1981, grid intersect U-13 identifies a young willow missing in 1997. Intersect RR-24 is at the top of a tall willow in 1981. The top is missing in 1997 owing to beaver cutting large stems for dam construction. Appendix A discusses grid analysis of photographs.

Figure 29—The meter board is used to aim the camera for consistent repeat photography. (A) Placement of the camera focus ring on the "1M", which puts the "1M" in the center of the picture (dashed lines). This orientation produces exact replication of repeat photographs as shown in B and C. The camera is focused on the "1M" placing it at the optimum sharpness for depth of field. With an f-stop of 8, everything in the picture will be in focus. This series is part of a study following logging effects on ground vegetation and stand structure (figs. 50 and 51): (A) 1977 just prior to a selection cut; (B) the summer after the cut and showing a two-turn skid trail crossing the meter board location; and (C) is 1995, 18 years later. Notice the color difference in A. The slide film was Ansacochrome compared to Ektachrome in B and C.

Figure 30—Photograph orientation using the camera focus system shown in **A** and placing it exactly on the “1M” of the meter board. **(B)** The focus is on the photograph identification sheet showing a maximum of ground vegetation. **(C)** The focus is on the distant horizon. **(D)** The meter board has not been set vertically, simply sloppy work. The tag on the meter board showing “2D” means this is photo point D at camera location 2. Five photo points are taken at this camera location. Notice the fadeout of the photo identification paper in B due to the light color. This will not happen with the medium blue shown in appendix C.

Use of double meter boards for identifying a topic of interest is illustrated in figure 31. The area is Lower Emigrant, one of three study areas on Emigrant Creek (fig. 14). When shrubs or other items exceed about 2 m in height, the double boards aid in following changes. Appendix C has plans for this double meter board, which folds in the center to provide a choice of either a 1-m or 2-m board.

Topic emphasis—Figure 32 illustrates four degrees of topic emphasis. A general topic, such as figure 21, may be represented by a 50-mm lens with meter board set at 14 m, a more limited topic is identified by the board set at 10 m, a closer view with the board set at 7 m, and a confined topic set at 5 m. The 5-m distance is recommended for shrub transect sampling discussed below.

Use of a 35-mm lens is illustrated in figure 33, a sagebrush-bunchgrass community. The meter board was placed 5, 7, and 10 m from the camera. The size of the meter board at these distances closely approximates a 50-mm lens at 7, 10, and 14 m, respectively.

Closeup photographs—Closeup photography is strongly recommended for topic monitoring locations. It is an integral part of transect systems. A view of ground conditions is taken with the meter board as a photo point locator and size control system. Figure 34 is a pair of closeup views from figure 20, Aug. '76, showing characteristics of the wet meadow at Pole Camp. Accompany each photograph with notes on the vegetation.

Some people might prefer a square target on the ground (fig. 24). In sparse vegetation this is satisfactory, but it may not be a suitable system in riparian areas such as that in figure 35. Figure 35A was taken 1 month after cows were removed, and figure 35B shows the same area 3 months later. The 4-dm-tall vegetation would completely obscure any kind of plot frame laid on the ground.

Figure 35 also illustrates the importance of standing 2 m away from the meter board and placing the "1M" of the meter board in the upper corners of photographs. In figure 35A, the bottom of the meter board can be determined whereas in figure 35B it cannot be seen. The entire meter board must fit in the frame if analysis of the images is to be possible. In figure 35C, the "1M" of the meter board is down almost 2 dm from the top of the frame; the bottom of the meter board, therefore is 2 dm below the bottom of the photograph, which makes accurate comparison between figures 35A and 35C difficult.

This concept of precise relocation of photo images can best be illustrated by use of lap dissolve 35-mm projection equipment. The objective is to hold the meter board absolutely still on the screen and show the vegetation change as each photograph is dissolved onto another.

Text continues on page 60.

Figure 31—Use of double meter boards for topic identification (in this case, impacts on willows from grazing livestock) and monitoring: (A) a single meter board's effectiveness in appraising shrub impacts, and (B) a better system for documenting shrub reaction to grazing. The camera is focused on the "1M" for consistent photo orientation.

Figure 32—Emphasis on topic identification is shown by distance from camera to meter board using a 50-mm lens on a 35-mm camera: (A) 14 m from the camera illustrating a close landscape view, (B) 10 m from the camera (a distance I have used as a standard), (C) 7 m from the camera emphasizing a rather specific topic, and (D) 5 m from the camera (a distance recommended for individual shrub analysis). Size and nature of the topic being monitored determine distance from camera to photo point. This scene is a testing layout where distances from the camera to meter board were evaluated, camera focal lengths were tested, and combinations of focal length and distance were compared (figs. 1-10).

Figure 33—Evaluation of a 35-mm camera for placement of a meter board to emphasize a topic. This is a transect in the Crooked River National Grassland in eastern Oregon. (A) Placement of the meter board 10 m from the camera. It is essentially the same as the 14-m distance with a 50-mm lens (fig. 32A). (B) A distance of 7 m, essentially similar to 10 m and using a 50-mm lens (fig. 32B). (C) Distance of 5 m, equivalent to 7 m with a 50-mm lens (fig. 32C). Comparison between figure 32 and this figure suggest advantages of pocket-size, quality 35-mm focal length cameras.

Figure 34—Technique for documenting ground vegetation using the meter board. Take one picture to the left and one to the right, keeping the meter board at the edge of the photograph. Stand 2 m from the board. Tilt the camera slightly off horizontal to make the meter board parallel with the side of the photograph. Place the "1M" top of the board in the upper corner of the view. The 2-m distance, using a 50-mm lens on a 35-mm camera, will assure that the bottom of the board is in the lower corner of the picture. When mounting the pictures, I overlap the meter boards so only one is showing. Set the camera to 3 m, which will put vegetation in focus from the bottom of the meter board to a distance of at least 2 m beyond the board. These are closeup views of figure 20, Aug. '76.

Figure 35—Riparian vegetation sampling on the Sandy Delta, south bank of the Columbia River, east of Portland, Oregon. A plot frame would be appropriate in photograph A with the 1-dm stubble height, which also permits visual estimation of the bottom of the meter board. The plot frame would not be visible in B or C. Exact reorientation of the photograph is essential: (1) The “1M” must be in the top corner of the view, (2) the bottom of the board must be in the lower corner, (3) the photograph must be taken from 2 m with a 50-mm lens on a 35-mm camera, and (4) the camera must be tilted slightly off horizontal to make the board parallel with the side of the view frame. In B, just 3 months later, grass is over 4 dm tall and effectively hiding the bottom of the meter board and any plot frame that might have been used. Problems with tall vegetation and exact photograph reorientation are shown in C, where the “1M” was not placed in the top corner of the view frame. Instead it is about 2 dm below the corner meaning the bottom of the board is about 2 dm below the bottom of the picture, an unacceptable rephotograph.

Photo Point Location

Photo point identifies the topic to be monitored (fig. 23); thus, it determines the camera location. One important factor is relocation of the meter board to orient later rephotography. In figure 27, the meter board was placed 10.3 ft from permanently marked camera location 1. The direction from the camera location to meter board was 115 degrees magnetic. The meter board location was marked with a fencepost, which severe flooding could remove; distance and direction to the meter board from a permanent location therefore are essential. The most foolproof method is a triangulation system using two permanent markers (fig. 27). The direction and distance from each marker are recorded. This triangulation method can replace the meter board within a decimeter of its original location. A diagram of the monitoring system should be part of the site map (fig. 15).

Camera Location

Selection of a camera location is determined by position of the topic (photo point) to be monitored. Consider how the distance from the camera to the meter board will influence topic emphasis (figs. 32 and 33). Both distance and photo point position are used to locate the camera for best documentation. Consider locating the camera where it will serve more than one photo point. This accomplishes three things: (1) efficiency is increased by using several photo points from a camera location, (2) the photo monitoring system is easier to relocate when one camera location will also locate two or more photo points, and (3) more information is obtained from the specific site being monitored.

Figure 35 shows "2E" on a meter board, meaning the fifth photo point at camera location 2. Using more than one photo point means careful location of the camera because it must be placed in a position to adequately depict several conditions specified in the monitoring objectives (appendix D). If a distance of about 10 m from camera to photo point is used, orient the camera location using a 10-m radius to encompass as many topics of interest as possible. The same distance from camera to photo point need not be the same for every photo point; for example, 8 m to photo point A, 10 m to B, and 12 m to C. However, the same distance to each photo point must be used for all subsequent photos: 8 m to A, 10 m to B, and 12 m to C.

Vegetation close to the camera location is another important consideration. Most authors who have rephotographed landscapes report vegetation grew up between the camera location and photo point, which obscured the view and rendered the rephotograph worthless. In many cases, the camera was moved to an unobstructed view (fig. 36).

Figure 26 illustrates a limited landscape photograph. The primary difference between this and a general site-specific view is the lack of a meter board for centering the camera view. Often, landscape views of an area must be reoriented in a manner similar to long-distance landscapes (fig. 16).

The need to map and stake both camera location and photo point is illustrated in figure 21. Treatment of the ponderosa pine-pinegrass community was so dramatic that relocation of photography without a map and permanent markings would be nearly impossible. Here stakes driven flush with the ground were relocated by use of a metal detector. Following treatment, fenceposts were placed at the stakes for easy relocation.

Figure 36—Effect of intervening vegetation between the camera and photo point. In 1975, the meter board was in full view at the start of the study to appraise effects of livestock on willow growth. By 1982, willows had grown between the camera and meter board requiring a change in the camera location. It was moved 1 m to the right. By 1996, willows had again obstructed the view so the camera location was moved 3 more meters to the right, a total of 4 m. This was a very poor camera location. Avoid locations where woody vegetation will obstruct the view and render future photographs difficult to interpret.

Riparian Areas

Riparian areas pose some particular problems in regard to camera location and photo points. Figure 23 documents streambank stability at Pole Camp. Figure 23A was the original camera location and photo point; however, the camera location was placed 2 dm from the bank. A winter ice episode eroded the bank, increased stream sinuosity, and destroyed the camera location. The camera had to be moved 1.2 m to the left and 1 m back from its original location. This resulted in a different view, as shown in figure 23B, which suggests that the streambank had moved 0.7 to 0.9 m to the right. But it had not moved to the right; the apparent movement was caused by a change in camera location—a situation to avoid.

**Relocation of
Repeat
Photography
Idiosyncrasies With
Compass Directions**

Riparian areas provide other challenges, particularly after floods. Deposition of silt is a valuable topic to document. Consider, when installing photo monitoring, pounding the fenceposts down to exactly the height of the meter board. When silt is deposited, the height of the meter board above the fencepost will be a measure of silt deposition.

Floods have other influences. Fenceposts may be torn out, thereby eliminating the photo point or camera location. Thus, documentation of fencepost position is essential (Governor's Watershed Enhancement Board 1993). Figure 27 illustrates a triangulation method for replacing washed out fenceposts.

Finding existing camera locations and photo points, whether landscape or site-specific, is sometimes difficult. Following are some suggestions for relocation.

In the Pacific Northwest, there is a 21-degree deviation from magnetic north. This can result in problems of two kinds:

1. The compass heading written on the map or layout instructions should be labeled as either true or magnetic. If it is a true heading, was the 21-degree deviation added or subtracted from the magnetic heading?
2. When searching for the camera location or photo point, be prepared to try four different headings.
 - A. Follow the heading and distance given. If the camera or photo point cannot be relocated, then . . .
 - B. Subtract 21 degrees from the recorded heading and look. If the locations still are not found, then . . .
 - C. Add 21 degrees to the given heading and follow that direction. If the camera location or photo point still has not been determined, presume that direction from the witness site to the camera location or photo point is reversed. In other words, a heading was taken from the photo point back to the camera location or camera location back to the witness site and recorded. Therefore . . .
 - D. Add 180 degrees to the compass heading and proceed with (A) through (C), above. This system has produced results for me 95 percent of the time.

**Field Book for
Rephotography**

A photo-monitoring field book is recommended for carrying the original and some intervening photographs into the field. If different people did previous photographs, you may discover some disorientation of subsequent views. For that reason, a copy of the original photograph is very important. Rephotograph the original and not the misoriented intervening photographs.

Figure 37—The author's system for finding camera locations and photo points. It is a pocket-sized set of photographs and directions mounted on cardboard (file separator thickness). (A) A left landscape view of the sampling area at Pole Camp; the right view is figure 26. A also locates camera locations 1 and 2. Camera location 1 has two photo points: D is Pole Camp dry and W is Pole Camp wet (fig. 20). (B) The upstream photo point taken from camera location 2 to S and illustrated in figure 23. Maps of this area are shown in figures 14, 15, and 27.

A system I devised is shown in figure 37 for the Pole Camp example. Figure 37A is a landscape view of the Pole Camp flood plain with camera locations and some photo points identified. It locates the left of two flood-plain scenes; the right is shown in figure 26. Both are mapped in figure 15. Figure 37B is a general view from camera location 2 to photo point S on the streambank, the scene in figure 23.

The pocket-size booklet has a picture of each camera location and photo point complete with directions from the witness site to camera location and orientation of the photo point. Cheap 5-ft fenceposts driven 2 ft into the ground are used to mark both camera locations and photo points.

Once at the area, review the photographs for changes in vegetation. Next, note the number of years since the last photograph, particularly if it was taken more than 3 years previously. The purpose is to evaluate changes in the vegetation that might make previous photographs difficult to interpret (figs. 21, 23, 36, and 38; app. E).

If camera locations and photo points are not marked, align items in the photographs as depicted in figures 16 and 38 and appendix E. Start in the center of the photograph to orient the direction of the picture as shown by line 1 (fig. 38). Then, orient items on the sides of the picture, shown by arrows 2 and 3, to triangulate the camera location. Move forward or back along the line to establish the distances shown at 2 and 3. This is the camera location and photo point direction. Mark them with fenceposts and add a meter board (photo point) location.

Multiple-Camera System

When both color and black-and-white photographs are to be taken, consider the camera system shown in figure 39. One camera is for black-and-white, the other for color. The cameras are the same make and model to simplify adjustment for lighting and distance. Appendix C has construction details.

Figure 38—Photograph reorientation uses a black-and-white photo on which a triangulation system is diagrammed. A center line (1) is established on the original photograph (A) for direction. The center line is identified by position of trees in the background and framing the picture with trees in the foreground. Then positions of items 2 and 3 at the sides of the picture are used to triangulate the camera location. Looking to the right, note the position of trees at arrow 2 while also looking left for tree positions at arrow 3. (B) Move forward and backward along the center line until items at arrows 2 and 3 are lined up. Try to include some unusual object in the photograph, such as the pair of stumps in the lower right corner. Photograph A is a pre-underburn condition, and B is postburn and salvage of killed trees. In B, note missing trees at arrows a and b, and a burned-out stump at arrow c.

Figure 39—A system for combining color and black-and-white photography. Both cameras are connected by strap aluminum 1/8 inch thick and 1 inch wide bent into a U-shape with holes drilled for mounting screws to connect the cameras. The cameras operate independently. Please consider using identical cameras so all setting controls are adjusted in the same way, greatly avoiding mistakes.

Review

Ground-based photo monitoring may be divided into two systems: (1) comparison photos whereby a photograph is used to compare a known condition (shown in the photo) with field conditions to estimate some parameter of the field condition, and (2) repeat photographs where several photos are taken of the same tract of ground over a period of time. Comparison systems can evaluate fuel loading and herbage utilization and monitor public reaction to scenery. Repeat photography was categorized into landscape, remote, and site-specific systems. Critical attributes of repeat photography are (1) maps to find the sampling location and of the photo monitoring layout; (2) documentation of the monitoring system to include camera and film, weather, season, sampling technique, and equipment; and (3) precise replication of photographs.

Figure 40—A general photograph taken in 1997 with the topic of streambank stability. It is part of a riparian study on Emigrant Creek, Snow Mountain District, Ochocho National Forest, near Burns, Oregon. The site is Pole Camp, a place livestock find highly attractive. The location of Pole Camp is shown on the map in figure 41. This streambank photo point is taken up stream from camera location 2 shown on the map in figure 42. Fencepost 1 is camera location 1, fencepost 3 is camera location 3 looking downstream at photo point S, S is photo point streambank, and fencepost W is photo point wet meadow. Other views of this streambank are shown in figures 23 and 49.

Figure 41—Local map showing location of the Emigrant Creek riparian study, Snow Mountain District, Ochocho National Forest, near Burns, Oregon. Three study areas are shown: Button Meadow at the head of Crowfoot Creek, Pole Camp shown in figures 20, 23, 26, 40, 44 and 49, and Lower Emigrant. This is one of two essential maps designed so people other than those installing the monitoring system can find the sampling sites. The other map is shown in figure 42.

Introduction

This appendix contains instructions on how to apply various photographic sampling methods designed to document changes in vegetation or soil on specific tracts of ground. It does not deal with general landscape photography or remotely operated cameras.

Nine photographic methods are discussed:

1. General photography where a scene is followed over time.
2. Topic photography dealing with a selected item, such as a streambank (fig. 40) or logging disturbance (fig. 21).
3. Grid analysis of photographs to document change in the selected topic or item.
4. Shrub sampling to record change in shrub profile area, usually accomplished by use of grid analysis.
5. Transect photography, in three dimensions, of square-foot plots.
6. Transect photo sampling of nested frequency plots.
7. Transect sampling of meter square (or 3-ft square) plots photographed at an oblique angle.
8. Photo documentation of tree canopy cover.
9. Photo records of herbage utilization using the Robel pole system.

All nine methods have several features in common, which are detailed in the following sections.

Selection of an Area

Selection of a monitoring area requires professional expertise liberally dosed with artistic finesse. The **purpose** for photographic monitoring is the most critical factor: Where in the landscape is the topic of concern, and once at the area, what kind of change should be documented? In some cases, *where* is straightforward; for example, documenting impacts of logging requires going to an area being logged (fig. 21) and documenting effects of beavers on a stream requires finding beaver dams. On the other hand, documenting impacts of livestock grazing requires understanding livestock distribution plus knowing the location of areas sensitive to grazing and the most critical season of use (figs. 20 and 40).

Once in an area, determine specifically what is to be documented for change. In figure 40 at Pole Camp, for example, the purpose was to document effects of livestock grazing on a riparian area. Pole Camp was selected because livestock preferred it. Specific objectives were to evaluate grazing effects on streambanks, willow shrub utilization, and differences in use between grass and sedge sites (Kentucky bluegrass by the fencepost on the right [1]) and sedge (at the fencepost in the background [W]). The topic in figure 40 is streambank stability.

Another example is the ponderosa pine stand shown in figure 21. In this case, the purpose for photo sampling was to document effects of a two-stage overstory removal and subsequent precommercial thinning on stand structure and ground vegetation. The site was selected based on the sale area. Stand conditions of open pine and clumped reproduction across an opening were chosen for the photo point. The opening was selected to avoid tree crown encroachment between the camera location and photo point and to appraise logging effects on livestock forage. It was photographed before and after each entry (fig. 21).

PHOTOGRAPHIC SITE DESCRIPTION AND LOCATION

Date 1974/10/5 Area Snow Mtn. Dist.
 Unit Pole Camp Observer: F. C. Hall
 No. of Camera locations: 5 No. of Photo points: 4
 Plant community Dry & wet meadow; willows
 Location: T. 19 S. R. 27 E. Sec. 29 SW of NE
 Location description S of rd 43; 0.25 mi W of junc. 43 & 4365 rds
off of turnout at E end of meadow
 Photo purpose: Document effects of change from season-long cattley
use to 3-pasture rest-rotation
 Discussion: Three photo points established in Oct 1974 documented
dry meadow (1), wet meadow with willows (W) and a fallen block of
wood at the stream edge (5) (1997) Flood of 2/96 washed out heavy
dams & created a new channel. Shrub sampling initiated 6/97.

MAP

Use back of sheet for additional details.

Figure 42—Filing system form "Photographic Site Description and Location" showing the monitoring layout for Pole Camp. Note in the lower left corner a reference to the junction of roads 43 and 4365 at 0.25 mi. Immediately opposite the road turnout is a 28-in-diameter lodgepole pine stump. An aluminum tag, orange for visibility, is attached to the stump with directions and distances to camera locations: a witness site. An additional map, noted by the square labeled "See detail attached," is shown in figure 27. It documents triangulation of the streambank photo point. Another note, "Shrub transect - see attached," installed in 1997, is shown in figures 64 and 65.

When to Photograph

When to photograph usually is determined by the activity being monitored. Pole Camp is part of a study evaluating effects of cattle grazing on a riparian area. Figure 20 includes photographs taken three times per year corresponding to livestock activity: June 15 before grazing, August 1 as cattle change pastures, and October 1 after animals leave the allotment. This three-season monitoring is repeated every year.

The ponderosa pine stand (fig. 21) illustrates a very different monitoring schedule. Photography was planned for the first week in August so that vegetation development would be consistent. Photographs were taken just before logging and in each of the two growing seasons afterward to document rapid changes in ground vegetation. Then a 5-year rephotographing cycle was established to follow slower changes in both stand structure and ground vegetation. The routine was repeated with the second logging and the precommercial thinning.

If vegetation is a primary topic, consider establishing a fixed date for rephotography. An established date has several advantages: (1) It offers an opportunity to evaluate seasonal differences in plant phenological development, (2) it provides a consistent reference for comparing change over several years, and (3) it establishes a consistent time interval over which change is documented.

Maps to Locate the Monitoring System

When the photo monitoring system has been established, prepare maps to locate the area and document the sampling layout. Assume that the person installing the monitoring program will **not** be the one to find and rephotograph the area. Provide maps and instructions accordingly. A local map showing roads and site locations is illustrated in figure 41 for Pole Camp, one of three locations for the Emigrant Creek riparian study.

After establishing the sampling system, establish a witness site or tree which marks the area. Identify it with a permanent marker, such as an orange aluminum tag, and determine direction and distance to camera locations or transects. Inscribe these on the identification tag. Next create a map of the camera locations and photo points or transects with directions and measured distances by using the filing system form "Photographic Site Description and Location" (fig. 42) found in appendix B. Note whether the direction is taken in magnetic or true degrees by indicating either "M" or "T." A 21-degree deviation in the Pacific Northwest must be accounted for. Measure distances between witness site, camera location, and photo points on the ground. Do not convert to horizontal distance.

Fenceposts or stakes—Monitoring, by definition, means repeated observation. Therefore, all camera locations, transects, and photo points must be permanently marked. The recommended method is with stamped metal fenceposts (fig. 40). These cost about \$2.25 each for a 5-ft size in 2000. Stamped metal has several advantages over strong T-bar posts: the former are flimsy and will bend if driven into by a vehicle or run over by an animal; they will bend flat and remain in the ground to mark the spot; they resist theft because they are just as difficult to pull out as a good fencepost but not worth the trouble; and they are easy to carry and pound. But the primary advantage of flimsy fenceposts is their visibility, as shown in figure 40. If visibility is not desired, steel stakes are a choice but require a metal detector to relocate.

DATE _____

CAMERA: 1 2 3 4 5									
PHOTO: A B C D									
E F G H I J									

Figure 43—An example of a photograph identification card to be placed in the camera view (fig. 44). This has been reduced to 60 percent. Appendix B has blank forms for reproduction onto dark blue paper. The best paper colors are Hammermill Brite Hue Blue® or Georgia Pacific Papers Hots Blue®. Light colored paper, common in the office environment, fades out under direct sun and should not be used.

Steel stakes often have been used and may be necessary in shallow soils or in areas that will be disturbed. If disturbance or shallow soils prevent use of fenceposts, the stakes should be driven flush with the ground. If left a few inches aboveground, stakes will damage tires, hooves, or feet and are often difficult to find. When driven flush with the ground, they require a metal detector for location (White's Electronics, Inc. 1996). Even then, the stakes must be of some mass for detection with a simple, \$250 machine. Angle iron should be 1 in on the angle and at least 8 in long. Cement reinforcing bar should be at least three-eighths of an inch in diameter and at least 8 in long.

One overriding consideration in photo monitoring is the requirement that the **same distance** be observed between the camera location and photo point for all subsequent photography of that sample. Any analysis of change depicted in the photographs can be done **only** when the distance remains the same. Therefore, always **measure** distance from camera location to photo point. A fixed distance for all photo monitoring is not required; this may differ from one photo point to another. Camera format also may change, such as first pictures with a 50-mm lens and next pictures with a 35-mm lens, but distance must remain the same. It can remain the same only if permanently marked.

Identification of Photographs

Identify each photograph by site name, photograph number, and date. Figure 43 is an example of a form for use in general or topic photographs (fig. 44). (Forms are in appendix B.) The critical factor is identification of **negatives** for color or black-and-white

CAMERA LOCATION AND PHOTO POINTS

Date 1997/6/17 Camera Location Witness Stump

 Unit Pole Camp Observer R. G. Hall
 Comments From rd junc. 43/4365, on rd 73 for 0.25 mi W. to
turnout on S. side road; witness stump 22" LP 20 yds. S
 slope 1 Aspect W Slope position bottom

Photo point A:
 Compass bearing: 237° M
 Distance:
Flood plain, left view
of Pole Camp study
site.
Mt. pine beetle killed
LP stand in background
1, 2, 3 are camera
locations; S & W are
photo points

Photo point B:
 Compass bearing: 270° M
 Distance:
Flood plain, right view
of Pole Camp study site.
1 & 2 are camera loca-
tions, D is dry meadow
photo point.

Figure 44—Filing system form "Camera Location and Photo Points" showing general photographs of Pole Camp taken from the witness stump: (A) left landscape and (B) right landscape noted in figure 42. Note repeat of fenceposts 1 and 2 in both pictures. Fenceposts identify camera locations 1, 2, and 3 and photo points D for the dry meadow, W for the wet meadow, and S for the streambank. Photo identification cards similar to figure 43, a form from appendix B, are at the bottom of each picture. The purpose of these photographs is twofold: (1) to illustrate the general sampling area and (2) to show location of the photo monitoring layout. Used in conjunction with the map in figure 42, someone other than the original sampling crew should be able to find and rephotograph this site.

pictures or digital images. Slides have borders to write on, but there is no similar space on negatives. Placing a photo identification card in each view as it is photographed assures a permanent record on the negative. Negative identification has been one my biggest problems!

Paper color is the next consideration. Plain white or light colors, common in the office environment, are not suitable because they are too light and will fade when photographed outdoors in full sunlight (fig. 30). The recommended paper color is either Hammermill Brite Hue Blue® or Georgia Pacific Papers Hots Blue® (app. B). Tests have shown these darker blue hues are superior to other vibrant colors such as green and yellow.

Description of the Topic

Describe what is in the scene to be photographed (fig. 44). This might include plant species, ground conditions, disturbances, or any other pertinent item. Appendix B contains forms with provision for recording these notes. For example, the filing system form, "Camera Location and Photo Points," is shown in figure 44 with two views of Pole Camp. Figures 46 to 48 (shown below), using the same form, illustrate mountain pine beetle effects on lodgepole pine over 13 years. And figure 50 (also shown below) is the "Photo Points and Close Photos" form for a general view and two closeup photographs of a ponderosa pine-elk sedge plant community in undisturbed condition. Recording of the percentage of cover for various items is recommended for good photo descriptions.

Filing System

Photo monitoring requires a way to file slides, prints, and negatives. My system is organized around each study with an expandable file used to contain everything (app. D).

The expandable files are placed in a file cabinet dedicated to sampling and organized first by geographic location and then by date for next photography. By filing studies geographically, generally around overnight facilities, travel planning is greatly facilitated. Noting the next photography date on each file helps with seasonal planning (app. D).

General Photography

General photographs document a scene rather than a specific topic or conditions along a sampling transect (discussed below). They are similar to landscape pictures in that they do not require a size control board (meter board) on which to focus the camera and to orient subsequent photographs. They usually cover an area of 2 to 20 acres and distance of 50 to 200 yards (figs. 26 and 44).

Concept

In many cases, general photographs document a scene in which a meter board cannot be placed where the camera can be focused on the "1M" of the board for distance and photo orientation (fig. 18). One use of a general photograph is shown in figure 26 depicting the setting of Pole Camp. Figure 44 is filing system form, "Camera Location and Photo Points," containing this and a second view of Pole Camp wherein the fenceposts marking camera locations and photo points may be identified. Another use is illustrated in figures 45 to 48 documenting effects of mountain pine beetle attack on lodgepole pine.

PHOTOGRAPHIC SITE DESCRIPTION AND LOCATION

Date Aug 1976 Area Camas Cr. Meadows
 Unit Ukiah District Observer: F.C. Hall
 Number of photo points 5 Plant community: lodgepole pine
 Location: T. 4S R. 33E Sec. 35 SW of SW
 Location description On Ore. hiway 244 between mile posts 15
& 16; 0.20 mi. east of junction with Bowman Cr. Rd.
 Photo purpose: Document effects of Mt. pine beetle
attack on bottomland climax lodgepole pine
 Discussion Some beetles noticed in 1975; this year major
kill (70%) of dominant lodgepole-needles red. Follow
for each year for 3 yrs, then about 5 yr. intervals.

Use back of sheet for additional details.

Figure 45—Filing system form "Photographic Site Description and Location" with map to locate camera locations and photo points documenting affects of mountain pine beetle on lodgepole pine. Two camera locations are shown. Figures 46 to 48 are from camera location 1 showing photo points 1A and 1B.

Equipment

The following equipment needs to be taken to the photography site:

1. Camera or cameras for different film or digital camera
2. Photograph identification form "Camera-Photo" (see index to app. B; the form itself is not labeled)
3. Clipboard and holder for the photo identification sheets (app. C)
4. Previous photographs for orientation of the camera
5. Filing system form "Camera Location and Photo Points" (app. B)
6. Fenceposts and angle steel stakes, sufficient for the number of camera locations desired, with pounder
7. A tripod to use for camera orientation while viewing the photographs

Technique

Select a scene that will meet your monitoring objectives. Describe it by using the filing system form, "Camera Location and Photo Points," and include plant species, ground cover items, disturbance, or whatever the topic of the photograph is. Photograph the scene.

Make maps of the location and layout of the scene on the filing system form, "Photographic Site Description and Location" (app. B; fig. 45).

Reorientation—Reorientation of subsequent pictures is a major concern if a meter board was not used originally to mark and establish photo orientation. Key items of each view have to be identified. For example, in figure 44, the tall tree in the right background of picture (A) is the same tree in the left background of picture (B). Panoramic views such as figure 44 always should have about 10 percent overlap between photographs.

Systems used for landscape photo reorientation, (see fig. 16) are of major help. On a black-and-white copy of the scene, mark reorientation items as shown in figures 16 and 38. With the camera mounted on a tripod, compare the picture in hand with the scene through the camera. Orient the camera accordingly.

Figure 37 illustrates a method for rephotographing general views. It shows 3- by 5-in photographs mounted on 5- by 5-in cardboard. Instructions are given under each picture for its location and orientation. These fit into a vest pocket for use in the field. Figure 44A is a recent picture of figure 37A.

Example—Figures 45 to 48 illustrate general photography to document effects of mountain pine beetle on lodgepole pine along Oregon highway 244 in the Blue Mountains of eastern Oregon. Figure 45 is filing system form "Photographic Site Description and Location" mapping two camera locations. Camera location 1 has two photo points (figs. 46 to 48) and camera location 2 has three photo points. Monitoring started in 1976 when beetles first attacked the stands.

Photo point B:
 Compass bearing: 240°M
 Distance: —
Salvage logged winter of '77-78, screen of dead trees retained

Figure 47—Stand conditions in 1978, 2 years after beetle attack in 1976. Photo point A shows 90 percent kill and massive standing dead fuel. Photo point B was salvaged in winter 1977-78. These photos were properly oriented to show tree tops and road center line.

Lack of a meter board on which to orient the camera is evident in figures 46 to 48. Treetops are cut off in figure 46, they are visible in figure 47, and again cut off in figure 48. It is important to precisely reorient repeat photos.

Text continues on page 92.

CAMERA LOCATION AND PHOTO POINTS

Date 9/18/5 Camera Location Ore 244 Series 1
 Area Camas Cr. meadow Number of Photo points: 5

planted) and growing
well

Figure 48—Stand conditions in 1991, 14 years after beetle attack and 13 growing seasons since figure 46. Photo point A shows most dominant trees are down, thereby creating severe burn conditions at ground level. Photo point B illustrates natural regeneration height growth. Compare photo orientation with figure 47, which is optimum; here, B has the tree tops cut off and about a 1/2 inch more pavement at the bottom. Orientation of repeat general photography requires skill and a set of orientation pictures similar to figure 37.

Topic Photography

Topic photography narrows the subject from a general view to a specific item of interest. It adds a meter board, or other size control object, to identify the photographic topic (figs. 40 and 49).

Figure 49—Topic photographs of streambank stability at Pole Camp. The specific topic of interest was fate of the fallen block of sod shown in 1977. Its fate might resolve the question of how fast the streambank will erode under change in livestock management from season-long use to three-pasture rest and rotation. By 1987, beavers had moved into the area raising the stream level, which converted Kentucky bluegrass on the fallen block to aquatic sedge. By 1997 the stream was dry because a flood in February 1996 washed out the beaver dams, cut a new channel, and drained late summer flows from this part of the stream. The block of sod is still present after 20 years of livestock grazing. See figure 23 for effects of a winter ice flood on the original camera location.

Figure 50—Filing system form "Photo Points and Close Photos" documenting effects of selection logging in a ponderosa pine/elk sedge community (fig. 29). This area had not been previously logged and had only sporadic sheep use because water was 1.5 mi distant. The general view is followed by pictures to the left and right of the meter board. The concept is to show both a general view and a pair of closeups to document change. Figure 29 illustrates what happened in this view after logging and 18 years later. Figure 51 illustrates the same series to the left of the meter board. Species are CAGE (*Carex geyeri* Boott, elk sedge), PONE (*Poa nervosa* (Hook) Vasey, Wheeler bluegrass), CARO (*Carex rossii* Boott, Ross' sedge), and FRVI (*Fragaria virginiana* Duchesne, strawberry).

Concept

A meter board, or other size control board, is placed at the topic to (1) identify the item to be monitored for change; (2) establish a camera orientation reference point for subsequent photography; (3) set up a constant sized reference by which change may be documented, for example by grid analysis; and (4) provide a point to focus the camera for optimum depth of field.

Figures 40 and 49 illustrate identification of a very specific topic, streambank stability. Figure 50 deals with a general view limited to area around the meter board, the topic being effects of logging and precommercial thinning on stand structure and ground vegetation. The purpose of topic monitoring is the primary factor in selecting a monitoring layout.

Effects of camera focal length and distance from camera to meter board to emphasize the topic are discussed in figures 31 to 33. When the distance from camera location to topic is the same (figs. 6 and 7), the 70-mm and 35-mm pictures can be enlarged or reduced to the same size meter board as in the 50-mm photograph (fig. 7). When cropped, all pictures will be the same. This can be done with prints from negatives or digital images; it cannot be done with slides. Try to use the same focal length for all subsequent photographs.

Equipment

The following equipment is required for topic photography:

1. Camera or cameras with both color and black-and-white film, or digital camera
2. Form "Camera-Photo," from appendix B for photograph identification, printed on medium blue paper
3. Forms from appendix B for site identification: "Photographic Site Description and Location," and photo points: "Camera Location and Photo Points"
4. Meter board (app. C)
5. Clipboard and holder for the photo identification sheets (app. C)
6. Fenceposts and steel stakes, sufficient for the number of camera locations and photo points desired, with pounder
7. Compass and 100-ft tape for measuring distance
8. Metal detector for locating stakes

Technique

Several steps are necessary to establish topic photo monitoring. Pole Camp (fig. 44) will be used as an example.

Define the topics of interest—At Pole Camp, primary topics of interest were effects of livestock grazing on streambank stability, differential utilization of dry and wet meadows, and impacts on willow shrubs. Next, the desired coverage of the monitoring area must be defined. How many streambank sites are desired? How many dry and wet meadows and where? How many shrubs should be monitored and where are they located? Note in figure 44A the distribution of willow shrubs and in figure 44B, the pattern of dry to moist to wet meadow.

Figure 51—The ponderosa pine logging depicted in figures 29 and 50. (A) Prelogging with elk sedge clearly dominant, (B) tracts and destruction of the elk sedge, and (C) 18 years later, still with very little elk sedge, only some squirreltail grass, and a browsed bitterbrush.

Figure 52—Filing system form "Photo Points with Overhead Views" documenting current tree canopy cover in a stand precommercially thinned 25 years previously. The form is in appendix B. Remember to make notes on what is in each photo.

Closeup photos—In many cases, details might be desired that are not accommodated by a meter board 7 to 10 m distant. Closeup photos, one on each side of the meter board, are recommended (fig. 34). After the general photo is taken, walk up to the meter board and photograph it on each side. With a 50-mm lens, stand 2 m away or with a 35-mm lens, stand 1.5 m away. Figure 34 illustrates the result with a 50-mm lens. The critical element is to always place the top of the meter board all the way up in a corner of the view (fig. 35). Details on the ground are shown in about a 1.5- by 1.5-m area on each side of the meter board (fig. 34). The concept is a general photo and two closeup photos to document change (fig. 50).

Figure 50 illustrates use of filing system form “Photo Points and Close Photos” (app. B) for mounting and filing topic photographs. It is the 1977 view of ponderosa pine shown in figure 29. Figure 51 has close views of general conditions, shown in figure 29 for prelogging, that were taken 1 year later and 18 years later.

Multiple photo points—Coverage could be either multiple photo points from the same camera location or multiple camera locations focusing on the same photo point. Figure 42 maps two photo points (D and W) from camera location 1 and two camera locations (2 and 3) focusing on one photo point (S). Figure 44 shows these camera locations and photo points. Advantages are twofold: First, relocation tends to be easier because only one point must be located that will serve two or more views, and second, one point showing several views tends to tie the sampling area together.

Overhead canopy—Overhead canopy pictures may be useful when documenting changes in tree canopy cover (fig. 52). A word of **caution**: camera focal length **must be the same** for all subsequent pictures because there is no size control board by which to adjust different photos taken at different focal lengths to the same size. Directions for overhead photography are contained in the “Tree Cover Sampling” section, later in this appendix.

Distance from camera to photo point—Distance between camera location and photo point is critical for any repeat photography from the camera location: It **must** remain the same. Exact replication of distance for all rephotography is the reason camera locations and photo points must be permanently marked in the field and their distances measured. I have found the best system is with flimsy fenceposts. The same distance is not required, however, for other photo monitoring. Figure 42 shows different distances of photo points from camera location 1.

An investigator may elect to do all three kinds of photography: topic view, closeups on each side of the meter board, and an overhead view for maximum documentation of treatment effects.

Analysis of Change

The meter board is used as a constant size reference point for analyzing changes. The recommended system is grid analysis, discussed next. A clear plastic form with site identification information is taped to the photo and topics of interest outlined. Then an analysis grid is adjusted to exactly match the size of the meter board in the outline and is printed on white paper. The outline form is taped to the grid, and grid intersects on and within the outlines are counted and recorded. Amount of change between photos can then be determined.

Photo Grid Analysis

Changes in vegetation, soil, fuel loading, streambanks, or other photographed items can be monitored by outlining the items on a clear plastic sheet that is then placed over grid lines. The method involves counting grid intersects falling on and within the outline and recording them. They are then compared to outlines of previous photographs of the same topic to estimate change. Each plastic sheet with its outlines becomes a database and must be identified. Outlines may be laid on top of each other and compared between photographs to visually assess changes.

Concept

The concept of grid analysis is based on a fixed geometric relation between camera and meter board to compare photographs. The basic requirement is a constant distance between camera and meter board (photo point) for the initial and all subsequent photographs. Different distances may be used for other photo points from the same camera location and at other camera locations depending on the topic of interest (figs. 49 and 50). An established camera height is desirable but not essential unless the grid is used to track change in position of items over time. Use of the same camera format, such as 50-mm lens on a 35-mm camera body, is recommended but is not required. Grids are designed to encompass a view limited to 13 to 15 degrees both horizontally and vertically. Views exceeding 15 degrees suffer from parallax caused by light refraction at the edges of a lens. Heavy lines surrounding the grid emphasize this limit.

A photograph of the topic (fig. 53, for example) is enlarged to 8 by 12 in for easy viewing. A clear plastic sheet, with information on date, site location, and topic, is attached to the photograph (figs. 54 and 55). The meter board in the photo is marked and the objects of interest outlined. Then a master analysis grid is adjusted for size by using the meter board on the outlined plastic sheet. For adequate precision in grid size adjustment, the meter board must occupy at least 25 percent of the height of the photograph; 35 to 50 percent is better. Adjustment in grid size requires measurement of the outlined clear plastic meter board (fig. 56), measurement of the meter board on a master grid (fig. 57), and reducing the size of the master to match the outline. Each individual picture must be measured for grid adjustment. Grids are reduced with a copy machine, printed on white paper, taped under the outlined clear plastic sheet, and grid intersects counted that fall on or within each outline (fig. 58).

Requirements

Requirements for photography suitable for grid analysis include the following:

1. Camera location and photo point (meter board) permanently marked so that exact relocation is possible. Consider use of cheap (stamped metal) fenceposts driven 2 to 3 ft into the ground for both camera location and photo point.
2. A size control board, such as a meter board, placed a prescribed distance from the camera for each photo point. The distance selected may be from 5 to 20 m depending on the meter board selected, a single meter board 1 m tall (figs. 49 and 50) or a double board 2 m tall (fig. 31). Distance for other locations may be selected according to the topic identified by the meter board. Make sure the visible part of the meter board occupies at least 25 percent of the picture height.

Text continues on page 103.

Figure 53—A1981 view of the Pole Camp wet photo point to be used as an illustration of grid analysis. This photograph will be compared to one from 1996. The first step is to attach a clear plastic outline form (fig. 54). Fill in the required site information and outline the shrubs (fig. 55).

Date _____ Observer _____ Cluster/Camera _____ GRID INTERSECT ANALYSIS Area _____ Unit _____ Transect/Photo _____		
---	--	--

Figure 54—Form used to identify photographic outlines. Reproduce the form on clear plastic overhead projection sheets. This form has been reduced to 85 percent of its size in appendix C. The full-sized form is suitable for color photographs of 8 by 12 in. Use of the clear plastic overlay is illustrated in figure 55.

Figure 55—Photographs to be evaluated by grid analysis: (A) 1981 (fig. 53), and (B) 15 years later in 1996. Clear plastic overlays (fig. 54) have been taped to each photo. Each overlay is a data sheet so it must have all information entered to identify the outlines. First the meter board is outlined on its left side and top. Then each visible decimeter line on the meter board has been marked and the decimeter number written on the overlay. Finally, each shrub has been carefully outlined and given either a letter or number identification. The next step is size adjustment of the analysis grid.

Figure 56—Measurement of meter boards for size adjustment of analysis grids: (A) 1981 and (B) 1996. Measure from the top down to the lowest visible decimeter mark to the nearest 0.5 mm, in these photos the 2-dm mark. Both measurements are 17.0 mm, which indicates the same distance from camera to board in both and consistent enlargement of the photos. The analysis grid (fig. 57) will have to be reduced in size to exactly match size of the meter boards in these outlines. An exact match is required for consistency in measurement between photographs.

Figure 57—The master analysis grid found in appendix C. Measure from the top of the meter board to the 2-dm mark used in the outlines. This measurement is 37.5 mm. Divide 17.0 mm from the outlines by 37.5 for a reduction to 45 percent of the grid. Print the grid on white paper at 45 percent of its original size. The outline is laid over the reduced grid to check on alignment of meter board marks. Minor adjustments in grid size are made so that marks of the overlay and grid meter boards match exactly (fig. 58).

Figure 58—Outline overlays placed on analysis grids: (A) 1981 and (B) 1996. The next step is to count grid intersects within each outline. When an outline crosses a grid intersect, such as the two intersects between shrubs 17 and 19, AA/18 and AA/19 in photo B, count the intersects for the shrub in front (shrub 17). Also count intersects along the grid edge, such as the five intersects in shrub 24 on line YY, photo B.

Figure 59—The filing system form "Photo Grid Summary" where number of grid intersects by outline are recorded. In figure 58A, shrub A had 21 intersects; 21 is entered for shrub A under 1981. The primary purpose for identifying each outline is to aid in recording the number of intersects. Notice that three more shrubs were identified in 1996 than in 1981, even though only 64 percent as many intersects were recorded.

Suggestion: When grid analysis is contemplated, clip vegetation away from the front of the meter board to expose the bottom decimeter line. This will provide for maximum precision in grid adjustment.

Photographed with a 50-mm lens on a 35-mm camera, a single meter board set at 10 m is 25 percent of the photo height (fig. 2A), at 7 m it is 36 percent (fig. 2B). A double meter board, 2 m tall (fig. 31), will be 25 percent of photo height at 20 m. The meter board is used to orient the photograph and adjust size of an analysis grid.

3. Orient the camera view on the meter board. Place the camera focus ring on the "1M" and focus (figs. 29 and 30). This accomplishes two things: (1) it provides for reorientation of all subsequent photographs, and (2) it provides for a sharp image at the topic marked by the meter board and an optimum depth of field.

The following items are required for grid analysis:

1. Photographs of the monitoring situation. Figure 53 is the wet meadow photo point at Pole Camp taken in 1981. It will be compared to a photo taken in 1996 to appraise change in shrub profile area. Print all photographs to be compared at the same size, preferably about 8 by 12 in, and in color for best differentiation of items to analyze.
2. "Grid Analysis Outline" (app. B) printed on clear plastic sheets used for overhead projection (for example, 3M® or Labelon® Overhead Transparency Film). Film is specifically designed for use with various printers (inkjet, plain paper, or laser). These sheets are imprinted with site information from the form in figure 54 and are used for drawing outlines around topics of interest.
3. The "Analysis Grid" form, shown in figure 57 (app. B). The grid must be adjusted in size to precisely fit each picture and outlined meter board (figs. 55 to 58). Instructions are given in the section, "Grid Adjustment," below.
4. "Grid Summary" form (fig. 59 and app. B).
5. Permanent markers for drawing on clear plastic (for example, Sanfords Sharpie® Ultra Fine Point Permanent Marker). Three colors are recommended when encountering overlapping outlines, as in figure 60, to aid in differentiating items. Colors suggested are black, red, and blue.
6. Good quality hand lens to help identify the periphery of items being outlined—in this case, shrub profiles.
7. A copy machine that will produce clear plastic overhead projection copies and can adjust size of the master grid to fit the photographs. Many copy machines can reduce to about 50 percent or enlarge to 200 percent. Be sure to use a copy machine that does not stretch the copy in either direction. Grids, adjusted for size and printed on white paper, are taped under each outline for analysis.

Figure 60—Outlines from 1981 (letters) and 1996 (numbers) overlaid for comparison of change in shrub profile. Note major changes in shrubs Q, V, and W, and a new shrub shown as 1. The dramatic reduction in shrub height of Q, V, and W from 1981 to 1996 was caused by beavers cutting the largest stems for dam construction.

Technique

Technique for grid analysis requires outlining the meter board and selected objects on the plastic overlay, “Grid Analysis Outline” form (app. B). The overlay has site information at the bottom because it becomes a permanent record of conditions on the date of each photograph (fig. 54).

Outlines on the overlay are interpreted by use of a grid that must be adjusted in size to exactly match divisions on the overlay meter board (figs. 56 and 58) in each photograph. The recommended procedure follows.

Outlining—Determine what is to be interpreted. In this example, change in willow profile area is the topic so all other items—grasses, sedges, forests and water—are not outlined. Decide whether individual shrubs will be evaluated or all shrubs lumped together. In this case, combined shrubs will be evaluated. Proceed as follows:

1. Fill out all information on the clear plastic overlay, because it becomes the permanent data record and must be identified (fig. 54). Date is the **photography** date, not when the outline was made.
2. Attach the plastic overlay to the photo at only one edge, such as the top, so that it may be lifted for close inspection of the photograph and then replaced exactly (fig. 55).
3. Using a straight edge, mark the left side of the meter board and its top on the overlay (fig. 55). Next, mark each decimeter division on the meter board and identify even-numbered decimeter marks by their number, such as 2, 4, 6, and 8 (fig. 55).

4. Starting in front, work systematically from left to right, outlining each shrub and labeling it with a letter or number (fig. 55). The primary purpose for identifying each shrub (or any outline) is administrative to assure that grid intersects inside an outline are not repeated or missed if interruptions occur during recording.

At times, identifying change in specific shrubs might be desirable. If so, each shrub identified in the initial photo will have to be identified in all subsequent photos and the letter or number used initially will have to remain exclusive to the shrub or to the location where the shrub used to be. This is best accomplished by shrub profile monitoring, discussed in the next section. Any new shrubs will require their own exclusive new identification.

5. When outlining, pay particular attention to the periphery of the shrub by following as carefully as possible the foliage outline. Do not make a general line around the outside of the shrub. Mark directly on the foliage, not outside of it. Check outlines by lifting the overlay to check on foliage and inspect with the hand lens.
6. Work back into the photograph. The letter inside the front shrub outline identifies the overlapping shrub (figs. 55 and 56). Using different colored marking pens may enhance overlapping outlines. Intersects often will occur under an outline. Count them for the shrub in front only (do not count the intersect twice).

Grid adjustment—Outline interpretation requires use of an analysis grid (fig. 57), whereby each grid intersection on or inside the outline is counted and recorded. The grid must be adjusted in size based on the meter board outlined on each overlay. Proceed as follows:

1. Measure height of the meter board as it appears on the overlay to the nearest 0.5 mm. If the bottom line on the board is not visible, measure to the lowest visible decimeter mark. In figure 56, it is 2 dm and measures 17.0 mm from top to 2 dm. Similar measurements between the 1981 and 1996 photographs indicate that distance from camera to meter board was the same and that both pictures were enlarged identically.
2. Next, measure height of the meter board on the master analysis grid. In figure 57, it is 37.5 mm from the top to the 2-dm grid line (second from the bottom).
3. Determine the percentage of change required for the master analysis grid: $17.0/37.5 = 45$ percent. On a copy machine, reduce the grid to 45 percent and print on plain paper. Overlay the outline on the grid to determine any additional size adjustment (fig. 58). This usually requires two or three trials.
4. Place the clear plastic overlay on the grid and assure that grid divisions exactly match those on the overlay meter board. Orient the overlay on the grid by using the left side of the meter board outline (fig. 58). Adjust the grid as necessary. When both overlay and grid meter board marks match exactly, tape the overlay to the grid.

Note borders on the grid. These mark the maximum 12- to 15-percent angle useful for grid analysis. Do not count intersects on outlines outside the grid.

5. On the filing system form, "Photo Grid Summary" (fig. 59), complete the required information and enter the year of the **photograph** in the "Date" column. This is the same date as on the plastic outline. List shrubs by letter or number in the "Item #" column. The form provides for recording intersects for three photographs. Note that items, shrubs in this case, are not required to have the same identification. Here, shrubs from 1981 are letters and those from 1997 are numbers because exact relocation of shrubs was not possible.
6. Starting in front and working from left to right, count the number of grid intersects on or within each outline. An intersect is where a horizontal and vertical grid line intersect. When the outline covers an intersect, count it for the shrub. Many times, the outline will separate two shrubs. Count the outline intersects for the shrub in front. Do **not** count the intersect twice. See figure 58A: intersect W-20 is on the outline for shrub "R" with shrub "Q" behind it. Record the intersect only for shrub "R." This is why outlining **on** rather than outside of shrub foliage is important. Do not try to count intersects for the shrub behind when they cannot be seen; for example, in figure 58A, intersects of shrub "Q" behind shrub "R" should not be counted. Count intersects on the edge of the grid but not beyond the grid even though the shrub or outline might extend beyond the grid, such as shrub W in 58A along the YY line. The grid defines the area of analysis, not the photo coverage.
7. Record the intersects for each shrub beside its letter or number (fig. 59). Recording by shrub letter or number will simplify record keeping. Disturbances or the need to stop can occur at any time, and a record is needed of shrubs already recorded and where to begin again. When finished, sum all the intersects (fig. 59): 1981 had 404 and 1996 had 318 intersects. Ask yourself if these are significantly different. The next section deals with analysis of change.

Note: Each picture is produced by enlargement of a negative. Seldom are two enlargements made at exactly the same scale even though the negatives might be precisely sized. Therefore, grids must be sized **independently** for each photograph (figs. 56 and 58).

Figure 58 compares outlines from 1981 and 1996. Visually, there is a difference in shrub profile area. These outlines are overlaid in figure 60 as one way to interpret change.

Analysis of Change

This section deals with analysis of change considering grid precision and observer variability. The grid monitoring system provides an opportunity to overcome both problems, which are primarily differences among observers. Let each observer do grid analysis on all photographs and interpret the results. The same personal idiosyncrasies will be applied in object outlining, grid sizing and placement, and interpretation of grid intersects, greatly reducing between-observer differences that affect interpretation of change.

Table 1—Effect of distance from camera to meter board on grid coverage at 10, 20, 30, and 60 m

Distance, camera to meter board	Ratio	Angle	Grid size at distance from camera of:			
			10 m	20 m	30 m	60 m
<i>Meters</i>		<i>Percent</i>	<i>-----Decimeters-----</i>			
5	1:50	2.0	2.0	4.0	6.0	12.0
7	1:70	1.4	1.4	2.8	4.2	8.4
10	1:100	1.0	1.0	2.0	3.0	6.0

Correct grid sizing and differences among observers influence analysis of change. Area within successive grid outlines may be digitized and compared. The data are entirely dependent, however, upon exact duplication of meter board outline size.

Grid precision—Percentage of photo height represented by the meter board is an important factor in precise fit of grids. The minimum is 25 percent and the optimum is 35 to 50 percent. A 35-percent meter board is 1.3 times more precise than a 25-percent board for grid adjustment.

Using a single meter board at 10 m (fig. 53), which is 25 percent of photo height, just a 0.5-mm difference in measurement at the meter board (17.0 vs. 17.5 mm; fig. 56) results in a 2.9-percent change in grid height. Grids 2.9 percent different in height also are 2.9 percent wider which results in a 5.9-percent difference in outline area. This same percentage applies to the number of intersects that may be within an outline.

A meter board occupying 33 percent of photo height would measure 22.5 mm in figure 56. A 0.5-mm difference here is only a 2.2-percent change in grid size. The 2.2 and 2.9 percent represent errors in measurement precision.

Distance from camera to meter board also affects precision of measurement on items beyond the meter board. Table 1 illustrates the effects of three distances between camera and meter board and how they affect grid precision at various distances from the camera. Because grids are adjusted to size at the meter board location, each grid is 1 by 1 dm at that location but this will change as distances increase.

A grid sized to a meter board 5 m from the camera measures 2 dm between grid lines at 10 m from the camera. This is two times greater than a grid sized at 10 m from the camera. At 30 m from the camera, a grid sized to a board 5 m from the camera will cover an area 6 by 6 dm. When sized to a meter board set 10 m from the camera, it will cover an area only 3 by 3 dm, one-half the dimensions and one-quarter of the area—a significant improvement in precision. Monitoring objectives help determine the optimum distance from camera to meter board as grid size adjustment and outline precision are balanced.

Observer variability—“Perfect” outlines are influenced by differences among observers.

1. Size adjustment of grids is influenced by observer skill. With a meter board at 25 percent of photo height, a 0.5-mm measurement difference of the meter board can mean as much as 2.9-percent difference in grid dimensions and 5.9-percent difference in area. Meter boards closer to 33 percent of photo height and larger photographs help to reduce this error. I recommend 8- by 12-in color photographs. A meter board at 33 percent of photo height would measure about 55 mm. A 0.5-mm measurement discrepancy would be only a 0.9-percent precision error.
2. The grid must be oriented exactly along the left side of the meter board as viewed (the observer's left side) and precisely at the top and bottom or lowest clear decimeter mark. Orienting precision is subject to observer skill.
3. Interpretation of what constitutes the periphery of an object profile (shrub in this case) is subject to observer variability. Choices have to be made about where to place an outline and how precise it will be, particularly for overlapping shrubs. An intersect is counted if the outline crosses it. The desirability of the topic being outlined tends to influence a person's willingness to include or exclude marginal parts. Outlining on clear plastic without grid lines tends to reduce observer bias.

A test was made in January 1998 of observer variability in outlining the shrub profile area shown in figure 53. Results of the seven observers are in figure 61. A 6- by 9-in color print with properly sized grid was provided. Observers placed the grid, outlined shrubs, and summarized intersects within each outline. Variation between observers was measured by the 5-percent confidence interval (CI). The CI also was calculated as a percentage of the mean: CI divided by the mean, then multiplied by 100 equals the CI% for each shrub, total of all shrub intersects, and an average CI. Low CI%, such as 5 percent (shrub H), is interpreted as low observer variability, and a change of more than 5 percent in intersects probably is a significant difference. High CI%, such as 25 percent (shrub B), means high observer variability and more than a 25-percent change is required to be significant.

Percentage of confidence intervals ranged from 4.2 percent (shrub L) to 54.4 percent (shrub D) (fig. 61). The average CI% among the observers was 15.4 percent, suggesting that a change of more than 15 percent in intersects is required. However, the CI% for total intersects of all shrubs combined was only 5.7 percent indicating good concurrence among observers.

The number of intersects in an outline seems to influence the CI%. A graph at the bottom of figure 61 show higher CI% with lower intersects per shrub.

Differences in shrub profile area are rather clear in figure 58. Profile area in 1996 was 79 percent of that in 1981 (fig. 59). The reader may wish to test this observer variability; count the shrub profile intersects in figure 58 and compare to the data in figures 59 and 61.

Figure 61—Summary of seven observers determining grid intersects on 18 shrubs from the same photograph. Variability among observers is characterized by the 5-percent confidence interval (5%CI) and is expressed by dividing the 5%CI by the mean intersects by shrub and multiplying by 100 (CI%Mean). The mean and CI%Mean are graphed by shrub.

Because CI% was rather high for individual shrubs, another observer variability test was conducted in winter 1999. Eight observers were provided with two photographs, one from 1975 and another from 1995, and asked to count total intersects of shrub profile. The CI% for 1975 was 7.5 percent and that for 1995 was 11.6 percent (fig. 62). The 1995 photo was more difficult to interpret.

The graph in figure 62 illustrates the mean, 5-percent confidence interval, and observer variability by year. Using the largest CI%, 11.6 percent, the averages are significantly different at the 0.5-percent level. Given a maximum of 12-percent observer variability here and 15 percent for total individual shrubs, a value greater than 12 percent of the average intersects is proposed as being significant at the 5-percent level of confidence for observer variability; for example, a mean of 384 intersects must change by more than 46 to say that the change was real and not due to observer variability at the 5-percent level of confidence ($384 \times 0.12 = 46.1$). This may be expressed as 384 ± 46 so that intersects greater than 430 or less than 338 may be considered a real change.

Beavers

Pole Wet - Shrubs

Figure 63— Regression of outline intersects from 1975 through 1997 for shrub profile changes at the Pole Camp wet meadow photo point. Intersects are total inside the grid area. Series 1 are the dates by year and series 2 are the intersects.

Studies, such as at Pole Camp where photographs are taken every year, are amenable to regression analysis of grid intersects. If the same person does the outlines, observer variability is greatly reduced. Figure 63 illustrates regression on shrub profile intersects at Pole Camp from 1975 to 1997 as determined from yearly photographs. Regression for the entire data set showed a decline of -0.63; however, when data were selected for the time of beaver activity in the area, 1983 to 1994, the regression was at -0.90, highly significant. Trendlines such as these seem very useful.

Grid Location of Items

Documenting change in position of items on a photograph requires precise photography. Three kinds of precision are required: (1) Distance between camera location and meter board must be the same for all repeat photos, (2) height of camera above the ground must be the same for all repeat photos, and (3) sizing and orientation of the grid must be precise.

Height of camera above the ground or orientation over the camera-location fencepost will change position but not size of objects. Figures 8 to 10 illustrate this relation by using the photo test view. Figure 10 overlays two sets of object outlines illustrating effect of camera position on location of objects and thus on the overlay grids. Reasons for this are shown in table 1.

Grid sizing and placement on the outline overlay, discussed previously, also are critical in detecting change in position.

None of these precision variables consider observer interpretation. They suggest that attempts to use photographs for monitoring change in position of objects seems questionable. If documentation of position change is desired, place the meter board in close proximity to the topic of interest, such as a streambank (figs. 23, 40, and 49), and measure from the meter board to the object of interest.

Shrub Profile Photo Monitoring

Change in shrub profile area can refer to either shrub utilization or shrub growth. It may be documented by repeat photography that uses grid analysis and horizontal camera orientation. Permanent camera locations and photo points, marked by either steel fenceposts or stakes, are required. Season of photography is a key factor in documenting change and causes of change in shrub profiles owing to shifts in leaf density.

Concept

Documenting change in shrub profile area involves photographing a shrub on two sides with the camera location moved 90 degrees for the different views. This photographs all profiles of a shrub. Camera locations and photo points must be marked with steel fenceposts or stakes to assure the same distance from camera to meter board for all future photographs. The same distance need not be used, however, for other camera locations. Adjust distance to suit the topic being photographed. Tall shrubs, where double meter boards are used (fig. 31), require a much greater distance than short shrubs.

The primary objective in monitoring change in shrub profile area or shape is to document utilization (reduction in area) or growth (increase in area). Thus, season of photography is of critical concern. If effects of animal browsing are the topics of interest, then photography both before and after utilization may be necessary. This

requires selecting two seasons to photograph, such as just before livestock grazing and immediately after. If livestock graze at different seasons in the same pasture over several years (as with rest-rotation systems), as many as four dates may be required to document grazing effects over the period. Other dates, established by local knowledge, probably would be required with wildlife.

If growth in shrub profile area were the topic of interest, then photography after termination of growth would be desirable. Dryland shrubs usually have a definite termination of growth, called determinate shrubs. Some riparian shrubs, such as many willows, continue to grow until environmental conditions (for example, frost) cause a termination in growth. These are known as indeterminate shrubs. For these, the season to photograph must be based on the phenological development of the shrub species under consideration.

Once photographs have been taken, use the "Photo Grid Analysis" procedure (previous section) to document and estimate change in shrub profile area and shape.

Requirements

All basic photo monitoring requirements must be met for relocating the monitoring area and maintaining the same distance from camera to meter board:

1. Establish a monitoring objective when selecting an area and shrub species to evaluate. Determine a photography date or dates.
2. Make a map to find the monitoring area (fig. 64) and a map of the transect layout (fig. 65). The transect layout must include direction and distance from the witness site to the first shrub photo point and then its two camera locations, and from there, the direction and distance to the next shrub photo point and its camera locations. All shrub photo points must be tied together for ease in future location. The transect layout need not, probably will not, be a straight line (fig. 65).
3. Placement of the meter board is of critical interest because it will be used to document changes in shrub profile. There are three concerns: (1) Placing the meter board far enough to the side of the shrub to allow the shrub to grow in crown diameter (figs. 66 through 69)—consider a distance that is half the current shrub crown diameter (fig. 66); (2) placing the bottom of the meter board far enough toward the camera to assure the lowest line of the grid will be **below** the bottom of the shrub if it grows—consider placing the 2-dm line opposite the current bottom of the shrub (figs. 67 through 69); and (3) placing the board in one location and moving the camera for a 90-degree change in view (figs. 66 and 67).
4. Select a camera-to-photo-point distance that will permit the shrub to grow in both height and diameter. Consider a distance where the current shrub is about 50 percent of the camera view height and 70 percent of the camera view width (fig. 67, B and C).

MAP

See attached page for details

Figure 64—The filing system form "Sampling Site Description and Location" identifies the Pole Camp shrub profile monitoring system. The first line of the form provides for circling one of several monitoring systems; here, "Shrub Form" has been circled. Information on the area is entered, and a map is drawn to locate the monitoring system. This shrub profile transect is one of several photo monitoring installations at Pole Camp. Figure 42 diagrams four other camera locations and four photo points. A note at the bottom of this map says an attached page has details. The page is shown in figure 65.

Figure 65—Details on the Pole Camp shrub profile transect. Instructions begin at camera location 1 for Pole Camp monitoring. The dry meadow photo point has been used as a camera location for a view down the transect (fig. 64). Direction in magnetic degrees and distance are shown for the five shrubs and the 10 camera locations.

Figure 66—System for location of a meter board when photographing shrub profiles. Figure 67 shows the views from photo 1A and photo 1B. Locate the board as follows: Measure the shrub radius in two directions at 90 degrees to correspond to the direction of photographs (12 in and 10 in). Move out from the shrub the same distances (12 in and 10 in) and locate the meter board at the intersection of the distances. This will place the meter board far enough to the side and front of the shrub so that the shrub can grow and still be analyzed with a grid.

Figure 67—The filing system form "Shrub Photo Transect" (app. C) showing Pole Camp willow transect 1 and both views of shrub number 1. The top photograph (A) was taken down the transect and B and C are of shrub number 1. Notes on the vegetation and item photographed are made opposite each photograph. The form provides for two views each of 10 shrubs with views down the transect from each end.

Figure 68—Grid analysis of shrub 1, view A, on the Pole Camp shrub profile transect. The outline form has been placed on the photo, information filled in, and the meter board marked. Outline as carefully as possible the shrub profiles. Do the same for photo B of shrub number 1 (fig. 69).

5. Try to select a single shrub or several shrubs separated from other shrubs in the camera view. If shrubs grow in profile area, their outer crown periphery may become difficult to separate from adjacent shrubs. Color photographs greatly aid in shrub-profile delineation.
6. Aim the camera so that the meter board is in the extreme left or right of the view (figs. 67 through 69). The shrub grid analysis overlay shows the meter board at the sides. Next, orient the camera so that the bottom of the meter board is just **above** the bottom of the camera view (figs. 67 through 69). Thus, a maximum amount of photo is allocated to current and future profile area of the shrub.

Notice in figures 67 through 69 the relation between placement of the meter board bottom about 2 dm below the bottom of the shrub and orientation of the camera at the bottom of the meter board. The objective is to document change in shrub profile both upward and outward.

When tall shrubs require double meter boards, such as in figure 31, the boards may be placed centered in front and the 2-m board grid (board in the center) used for analysis.

Figure 69—Outlines of view B, shrub 1, on the Pole Camp shrub profile transect. When two shrubs are present, separate their outlines as shown. Information on the bottom of the clear plastic overlay must be filled in for each photo. Remember to outline and mark the meter board.

7. Fill out and place the photo identification card, "Shrub Photo Sampling," next to the meter board (figs. 67 through 69). This is essential for labeling each slide, negative, or digital image.
8. Focus the camera on the meter board to assure greatest depth of field for the shrub. Then swing the camera either left or right to place the meter board at the side.

Equipment

The following equipment is required for shrub profile sampling:

1. Camera or cameras with both color and black-and-white film or digital camera
2. Forms from appendix B for photo and transect identification: "Shrub Photo Sampling" printed on medium blue paper, data and photo-mounting form "Shrub Photo Transect" printed on medium yellow paper, the "Grid Analysis Outline" printed on clear plastic, and "Analysis Grid-Shrub Analysis" adjusted in size and printed on white paper
3. Meter board (app. C)
4. Clipboard and holder for the photo identification sheets (app. C)

5. Fenceposts and steel stakes sufficient for the number of transects desired: 1 fencepost and 2 steel stakes per shrub; for a 10-shrub transect, 10 fenceposts and 20 stakes required; include a pounder
6. Compass and 100-ft tape
7. Metal detector for finding camera locations

Technique

The technique for shrub profile monitoring combines a transect system with principles discussed under “Photo Grid Analysis,” above. A primary objective is to monitor **change** in shrub profile area and not to measure canopy cover of shrubs or shrub profile area per acre. Shrubs therefore are objectively selected for photography. The following technique emphasizes this selectivity.

1. Locate the area of consideration. Walk the area to select shrubs to be monitored. In many cases, shrub distribution does not lend itself to straight line transects, particularly in riparian areas with winding streams. Ask, “Why am I concerned with change in shrub profile area?” Is it to appraise utilization, assess vigor, or document increase in profile area? Is the location of shrubs important, such as shade along streams?
2. Mark each shrub to be photographed with steel fenceposts or a combination of posts and stakes: a fencepost to mark the meter board and two more posts or stakes to mark camera locations that view the shrub at 90 degrees (two different sides). Whenever possible, select a single meter board position that will accommodate the two camera locations (figs. 66 through 69). Measure distances from the photo point to camera locations.
3. After marking all the desired shrubs, diagram the transect layout (fig. 65). Take a direction and measured distance from the witness mark to the first shrub meter-board position. Diagram the two camera locations with direction and measured distance from the meter board. Then take direction and measured distance from the first shrub meter board to the second, documenting direction and distance of the camera locations. Continue to the end of the transect. Remember to indicate magnetic or true north.
4. When ready to photograph, fill out the filing system form, “Shrub Photo Sampling,” for photograph identification (app. B) as shown in figure 67.
5. Take a general picture of the transect by setting the meter board at shrub 1 (fig. 67A). Stand 7 to 10 m from the board and place the “Shrub Photo Sampling” form in view (fig. 67A). Stake the camera location and add to the sampling layout diagram. Reference it to the witness location.
6. For each shrub, place the photo identification form, “Shrub Photo Sampling,” next to the meter board (fig. 67, B and C). The form has a shrub number and letter for 10 shrubs. Match the shrub number and letter on the form with the transect diagram and circle it (in fig. 67B, 1A is circled).

7. Photograph the shrub. Then move to the second camera location, turn the meter board and the photo identification form to face the camera, cross out the last shrub view on the form, and circle the current one. In figure 67C, 1A is crossed out and 1B is circled.
8. Make notes of what is in the view (fig. 67). Identify the shrub, list herbaceous vegetation, and note anything of interest, such as browsing and by what.
9. Then move to the next shrub and repeat the process until completed.
10. Mount the photographs as shown in figure 67. The filing system form, "Shrub Photo Transect," is designed for 3- by 4½-in photos.
11. Conduct grid analysis of the pictures as discussed next.

Shrub Profile Grid Analysis

A complete review of the "Photo Grid Analysis" section, above, is necessary to do this evaluation. Only highlights specific to shrub-grid interpretation are presented here.

Print the photographs to be analyzed, in color, at 8 by 12 in. From appendix B, select the "Grid Analysis Outline" form (fig. 54) and duplicate on clear plastic. Fill out all information at the bottom of the outline form. The completed outline becomes a data file and must be identified. Tape the outline form to the photograph along one edge or top so that the outline can be lifted for close inspection of the photo and then replaced exactly (figs. 68 and 69).

Outline the shrub or group of shrubs in the photo. Do not try to guess the outline of a shrub hidden behind another. Outline, only what can be seen. Be as precise as possible.

Next, adjust the grid (with meter boards at each side) for shrub analysis (app. B) to exactly match the outline meter boards as discussed in "Photo Grid Analysis" (figs. 56 and 57). Tape the outline form to the grid (fig. 70).

Count intersects within each outline including intersects falling under an outline line (figs. 58 and 67), and enter on the filing system form, "Photo Grid Summary" (fig. 71). Please refer to the section "Photo Grid Analysis," and within it "Analysis of Change, Observer Variability," for a discussion of what constitutes a significant change in shrub profile area.

Test your own observation skills. Count grid intersects in figure 70 and compare to the results shown in figure 71. Expect a difference of three to six grid intersects.

Figure 70—Grid outlines for shrub 1, views A and B on the Pole Camp shrub profile transect. Grids have been adjusted for size by the outlined meter board. Outlines are then taped to the grid. Count the grid intersects and record on the filing system form "Photo Grid Summary" (fig. 71).

PHOTO GRID SUMMARY

CONTINUE

Transect Photo Sampling

The historical purpose for transect sampling was to document change in vegetation and soil caused by livestock grazing, commonly called range trend analysis (Parker 1954, Parker and Harris 1959). The Parker three-step method (Parker 1954) was designed for this purpose. It used a 0.75-in diameter loop dropped at each foot along a 100-ft line. The system was supplemented by photographs taken of the transect from the 0- and 100-ft ends with additional closeup pictures of a 3- by 3-ft square at each end.

By 1970, the system had been installed at 16,500 locations and reviewed by the Rocky Mountain Forest and Range Experiment Station (Reppert and Francis 1973). The findings suggested that photographs are the most valuable part of the system. Photos (1) documented transects across two or more sites, (2) helped to evaluate species identification, and (3) were used to validate interpretation of measured data through a four-step process.

Based on these findings, Hall (1976) developed a photo monitoring method, which has been updated for presentation here.

Five kinds of photo transects will be discussed and illustrated: (1) 1-ft² frequency photographed with a stereo attachment on the camera (or photographed without the stereo), (2) nested frequency using four plot sizes in a 0.5- by 0.5-m frame, (3) 1-m² plot frame photographed at an angle, (4) vertical photographs of tree canopy cover, and (5) measurement of herbaceous stubble height using the Robel pole system. All five may be applied on top of any three-step transect or they may be installed in new areas for any documentation of ground vegetation and soil surface monitoring. The following factors apply to any transect system.

Locating a Sample Area

The introduction to this appendix discussed selection of an area and when to photograph. Probably the most important of these suggestions was to **define a purpose** for monitoring. In addition, several other elements might be considered: livestock grazing, wildlife distribution, and planned and unplanned disturbance because the investigator must be guided by factors not under their control. Transect photo monitoring is not limited to livestock effects analysis.

Livestock considerations—The three-step sampling system (Parker 1954) was designed to evaluate livestock grazing impacts on vegetation and soil. Instructions called for one to three transects. The objective was to attain 60 or more hits on vegetation with a 0.75-in loop. If more than 60 hits were not recorded on the first transect, then a second or third transect was installed until either 60 hits were obtained or three transects were established. Each set of transects was called a cluster. Nested frequency, also an appraisal tool for livestock impacts, requires five transects.

Location of transects has three primary requirements:

1. The site under each transect must be homogeneous. If an entire cluster of two to five transects is to represent a single site, vegetation and soil surface conditions under each of the transects must be homogeneous and similar to each other.

2. The kind of site selected should be one sensitive to livestock use. For example, in a complex meadow where dry meadow around the edge grades into moist meadow, which finally grades into wet meadow, the most desirable sampling location would be in the dry meadow because it is most sensitive to livestock use.
3. Locate the sample in an area best representing current livestock utilization.

These three criteria generally will satisfy the objectives of monitoring management effectiveness by photographic documentation of conditions; evaluation of sensitive areas which, when indicating an upward trend, imply that less sensitive areas are in a faster upward trend (or are in better condition); and distributing sampling locations on a least-cost or cost-effective basis.

The most difficult aspect of sample location deals with suitable representation of current livestock activity. Samples on a range area (allotment) grazed season long may not be adequately located or sufficient in number for the same area under rest-rotation grazing. Furthermore, locating a transect may be difficult in an allotment that has had a major change in management—for instance, from season long to rest-rotation—until livestock distribution over an entire grazing sequence has been evaluated. Selection of a site sensitive to livestock use in a unit under spring grazing might be quite different from that selected in the same unit under fall grazing.

Locating a sampling site requires a great deal of professional expertise liberally mixed with artistic finesse. Investigators must understand seasonal and topographic effects on livestock distribution, seasonal effects on plant community, and soil sensitivity to grazing, and they must have a critical eye for site homogeneity.

Wildlife considerations—Locating transects or clusters suitable for monitoring impacts of wildlife, including big game, on vegetation and soil requires knowledge of animal distribution and most critical season of use. Wild animals may be year-round residents or may be moved by snow or other weather conditions. The investigator must determine which season is most critical and where the animals are at that season for both transect or cluster location and season of sampling.

Planned disturbance—Planned disturbance sampling is where a treatment is prescribed and the area is sampled before and after implementation. Figure 21, a logged and precommercially thinned ponderosa pine stand, is an example of planned disturbance sampling. Two important factors to consider are (1) where to locate the sampling transects so they best represent effects of the treatment, and (2) use of camera location and photo point stakes pounded flush with the ground to resist mechanical displacement. These require use of a metal detector to relocate (White's Electronics, Inc. 1996). Use maps with directions and measured distances to aid in relocating stakes.

Fenceposts, flimsy or strong, used in any kind of disturbance other than prescribed fire, tend to do two things: (1) they bias operators of equipment to stay away from the posts, and (2) they may be removed completely from their location making exact replacement of camera locations and photo points nearly impossible. Prescribed fire

sampling, however, might well use fenceposts, particularly for photo point locations. Pound the fenceposts down to the exact height of the meter board. Then photograph the fire as it passes the fencepost to document fire intensity, flame length, and burn aftermath. Coordination with the fire boss on transect layout and direction given topography and fire behavior might be advisable.

Unplanned disturbance—Unplanned disturbance, such as fire, blowdown, or flood, generally preclude predisturbance transect or cluster installation. Care should be taken to select areas where change is most critical or where postdisturbance activity, such as salvage logging, most likely would occur. If activity is probable, consider use of steel stakes driven flush with the ground and a metal detector to find them

Maps—Each cluster should have two maps: one to find the monitoring area (fig. 72), and another of the cluster layout (fig. 73). A blank form for “Sampling Site Description and Location” is in appendix B.

To use the “Sampling Site Description and Location” form shown in figure 73, circle the type of sample in the (top line), in this case “1 sq. ft.” Most items are self-explanatory such as entering the date installed, the name of the area, and the allotment. Grazing system should be entered, such as season long, enclosure, deferred-rotation, elk fall range, deer fawning area, etc., and the date when initiated or season of use. Circle the kind (or kinds) of animals using the sample area.

Describe location with both standard survey nomenclature and a description of where the sample is located in relation to land, vegetation, or road features. Describe it as if you were telling someone how to find it. Then diagram the sample layout in the map space (fig. 73). Note, location of identifiable features, compass headings as either true (T) or magnetic (M), measured distances, transect location and orientation, and the 0- and 100-ft ends. With transects laid end to end, continue the sample layout map on the back of the form (fig. 74).

The front side of the form is for a site description (fig. 73). Enter elevation and percentage of slope. Then circle the item best describing aspect, slope position, micro (within one acre) and macro (within one section) topography, kind of soil deposition, soil parent material, and kind of restriction to rooting depth (if there is a restriction within 5 ft of the soil surface). Enter depth to restriction and rooting depth. Circle items describing soil compaction, soil stone, and texture. A space is provided for comments not otherwise addressed.

Note: A single site description presumes all transects are on the same site. If they are not on the same site, fill out a new form for each different site.

Choice of film—Choice of film is a concern. Photo trend sampling is designed to measure change in vegetation and soil over time. Photographs taken 5, 10, or 15 years earlier are compared to current photographs. Film therefore must be selected that will retain its sharpness and clarity for a long time. Black and white film should be the first choice, but it can be supplemented by color film.

Text continues on page130.

Figure 72—Ranger District map locating the Madras Exclosure and three range trend sampling clusters having three transects each in the Crooked River National Grassland. Cluster number 3, transect 1, will be used to illustrate photo sampling of square-foot frequency, nested frequency, and square-meter systems.

MAP

Figure 73—Filing system form "Sampling Site Description and Location" for finding the Madras Exclusion cluster 3. The first line lists a choice of sampling systems. Circle "1 sq. ft." Fill in the required information as shown. After laying out the photo sampling system, plot it in the map space provided. If several transects require more space, use the form back (see fig. 74). Take direction and measured distance between the witness point (Crooked River National Grassland sign) and the first transect (185 degrees magnetic, 70.0 ft). Next take direction and measured distance to the 100-ft end of the tape (170 degrees magnetic, 99.6 ft). The 100-ft end-stake is at foot mark 99.6. See figure 74 for continuation of the map.

Figure 74—Map on back of figure 73 showing location of transects 2 and 3. When distances are measured, as shown here, use feet and tens of feet, for example, 50.0 ft between transect 1 at its 100-ft end and transect 2 at its 0-ft start. Then 99.7 ft between the 0-ft stake and the end stake located at foot mark 99.7 for transect 2. Continue for transect 3.

Film with an ISO rating of 100 or better should be used, particularly in forested conditions. A film of ISO 160 will have good contrast and fine grain. ISO ratings up through 400 may be considered. Higher ISO ratings mean smaller f-stops (higher f-number) and produce greater depth of field. Photos taken with films rated higher than ISO 400 will be grainy and nullify lens sharpness.

Digital cameras should have 2.1 megapixels or more. Graininess of images from cameras of 1.6 megapixels or less usually precludes accurate analysis of prints.

Season of year—Season of year for photography depends on objectives and past history. Reppert and Francis (1973) recommend repeat sampling within plus or minus 2 weeks of the original date. When placing the 1-ft², nested frequency, or 1-m² transects on top of existing three-step transects, date of sampling should be governed by the original readings. For newly established transects, date of installation should be governed by plant growth development (phenology) and season of critical concern. In general, a good time to sample is when plants are well into flowering or just completing their maximum seasonal growth.

Transect Installation

Document the direction and measured distance from a witness site to the 0-ft end of the first transect. Set a fencepost to mark the transect. Drive stakes to leave about 6 in aboveground onto which the 100-ft steel tape is clamped. Vice grips are very convenient. The 0-ft mark on the tape is aligned with the first angle iron stake and clamped in place. A mid-stake is located between foot marks 50 and 51, and the end-stake is located between the 99- and 100-ft marks and clamped in place. Make sure the zero end is labeled and that 0- and 100-ft ends are properly documented on the map (figs. 73 and 74). Mark both ends with fenceposts for easy relocation.

In disturbance sampling, presample the area with 6 in of stake aboveground for fastening the steel tape. After sampling, drive the stakes flush with the ground. For postsampling, plan on adding a stake nested inside the flush stake extending 6 in aboveground on which is clamped the 100-ft steel measuring tape. Relocation of the flush-pounded stakes will probably require a metal detector (White's Electronics, Inc. 1996).

From the 0-ft stake, record direction (note true or magnetic) and measured distance to the 100-ft steel stake (figs. 73 and 74) for each transect. Tie the transects together for easy relocation by direction and measured distance from one to another (fig. 74). Always record location of both the 0- and 100-ft ends.

Every transect should have a photograph taken from both the 0- and 100-ft ends (figs. 75, top, and 77). Each photograph down the transect should be identified with the cluster-transect form (app. B). Place the identification form at 15 ft, a size control board at 33 ft, hold camera at eye level, and photograph the transect with the camera focus system on the size control board's "1M" and the photo identification sheet at the bottom of the picture (fig. 75). Repeat this procedure at the 100-ft end of the tape by placing the identification sheet at foot mark 85 and the size control board at foot mark 67 (fig. 77).

133

The cluster-transect identification form (app. B) is used for both the 0- and 100-ft ends of a transect. Print information in large letters similar in size to those on the form. This size can be read on the photographs (figs. 75 and 77). Circle "0" in upper right corner for the 0-ft end (fig. 75). After taking the picture, cross out the "0" and circle the "100" for the picture at the 100-ft end (fig. 77).

A size control board is required (specifications in app. C). The illustrations in figures 75 and 77 have a size control board marked with "1M" (indicating 1 m) and decimeters labeled as 2, 4, 6, and 8. Use of a size control board has several purposes: (1) depth of grass, height of shrubs, or other items can be estimated; (2) when the camera focus system is placed on the "1M," pictures will be consistently oriented both horizontally and vertically for easy comparison; (3) focusing the camera on the "1M" assures sharp picture clarity and greatest depth of field at the meter board; and (4) grid analysis may be performed if desired.

General transect photographs from the 0- and 100-ft ends should be taken with the three-dimensional attachment (fig. 78) on 1-ft² transects (fig. 75 through 77) if available, otherwise with a 50-mm lens. For other sampling, use a 50- or 35-mm lens for nested frequency, 1-m², and canopy cover. A 50-mm lens should be used with Robel pole to adequately document pole divisions. In addition, a standard photograph (without 3-D) is highly recommended on 1-ft² transects to encompass a broader horizon of the plant community and, when color slides are produced, to use in slide talks dealing with range trend (fig. 77).

Transect data forms—Forms are provided in appendix B. The series of "Photo Trend Sample-..." forms double as both data forms and a filing system for the photographs. Another form identifies the cluster and transect photograph in letters large enough to be read on the negative. The plot identification form identifies each plot and labels it on the photo negative. Because these forms are used in the field, they should be printed on a paper color that is easy on the eyes and will not burn out in photography under direct sun. "Photo Trend Transect" forms should be printed on medium yellow paper, such as Champion Goldenrod® or Hammermill Copy Plus Goldenrod®, which have been found quite acceptable. Light yellow paper, common in the office environment, is less satisfactory. Transect and plot photograph identification forms will resist fading out under direct sun if printed on medium blue color paper. Tests have shown that Hammermill Brite Hue Blue® or Georgia Pacific Papers Hots Blue® are most useful.

One-Square-Foot Plot Transect

One-square-ft sampling employs a square-foot plot placed every 5 ft along a 100-ft transect for a total of 20 plots. It is designed to document changes in species, their density, and frequency as a means to estimate change in vegetation and soil surface conditions.

Concept

Each 1-ft² plot is photographed in stereo to provide a permanent, visual record of vegetation and soil surface conditions. At the same time, each plant species rooted in the plot is recorded and presence of bare soil, gravel (1/8- to 3/4-in diameter), rock, litter, and cryptogams are noted. At a later time, the same transect will be

Figure 78—Camera using a 50-mm lens with stereo adapter mounted (**A** and **B**). This a Honeywell Pentax Stereo Adapter® with the connection plate removed because it will not fit on a Canon® camera. (**C**) The connection plate and its cover are shown removed. In **B**, the stereo system has been taped to the camera over a filter. It must be aligned horizontally with the camera (**A**). (**D**) The complete system includes the stereo adapter and slide viewer.

reread and rephotographed to provide a comparison set of pictures and data. Range trend is interpreted by comparing original and followup photos and data of each 1-ft² plot to appraise changes in species presence, density, basal area, frequency, shrub and tree line intercept, and soil surface characteristics.

Photographs are used to measure or estimate vegetation and soil parameters, aid in evaluating plant identification, facilitate illustration of range trend or lack of trend, and reduce observer variability in comparing transect readings taken at different times. Anybody can compare and measure the difference between photographs.

Stereo photographs greatly aid species identification and interpretation of vegetation and soil parameters. Try evaluation on one-half of a stereo pair—then view it with a stereoscope (fig. 75)!

Equipment

The following equipment is required for 1-ft² sampling:

1. Camera or cameras with color and black-and-white film and stereo adapter (fig. 78)
2. A 1-ft² plot frame (app. C)
3. Forms from appendix B: for photo identification “Cluster-Transect” and “Square Ft Frequency” printed on medium blue paper; and the data and photo-mounting form “Photo Trend Sample - 1 sq. ft.” printed on medium yellow paper
4. Meter board (app. C)
5. Clipboard and holder for the photo identification forms (app. C)
6. Compass and a 100-ft steel tape with clamps or vice grips to clamp onto angle iron stakes
7. Fenceposts and angle iron stakes sufficient for the number of transects desired: two fenceposts and three angle iron stakes per transect and a pounder
8. Metal detector for locating transect stakes

Technique

Map the location of the transect cluster (fig. 72). Establish the transects and map them on the filing system form “Sampling Site Description and Location” (fig. 73). If slope exceeds 10 percent, orient transects on the contour so that uphill is left of the transects when viewed toward the 100-ft end. Placing plot frames and photographing uphill is easier than working downhill. Fill out information on the form and circle “1 sq. ft.” on the top line. If transects fall in a line, continue the map on the back of the form (fig. 74).

A three-dimensional adapter for 35-mm cameras with 50-mm lenses is desirable for both general and 1-ft²-plot photographs (fig. 78). Such adapters may not be available, however. If not, use a 50-mm lens in preference to a 35-mm for best detail resolution. Take general pictures from the 0-ft (fig. 75, top) and 100-ft ends (fig. 77) to show vegetation prior to trampling from placing and photographing the 1-ft² plot (figs. 75 and 76).

The filing system form, “Photo Trend Sample – 1 sq. ft.” (app. B), is illustrated in figures 75 to 77. It should be printed on medium yellow paper such as Champion’s or Hammermill’s Goldenrod® to ease eyestrain. It is used to diagram plants and mount photographs of the 20 plots. Fill in date, area (Crooked River N.G.), allotment (Madras grazing unit), cluster number (3), transect number (1), and the investigator’s name. “Season of use” means when during the previous 12 months the area was used, such as season long, spring, summer, fall, or winter. The “% use” is the average utilization at the time of sampling. “Grazing system” means the kind currently being used, such as season long, rest-rotation, or alternate year. Any comments may be made under “Remarks” (fig. 75) or “Comments” (fig. 77).

Transect photos are identified by the filing system form “Cluster-Transect” (figs. 75 and 77). It should be printed on medium blue paper. Fill in the date (97/3/22), circle either “0” or “100” (fig. 75 is 0, and fig. 77 is 100) to indicate which end of the transect is being photographed, area (CRNG), allotment (Madras), cluster number (3),

and the transect number (1). For the downtransect photo, place the camera at the 0-ft stake, photo identification form at 15 ft, and the meter board at 33 ft; for uptransect photos, camera at 100 ft, photo identification form at 85 ft, and meter board at 67 ft.

Each square-foot plot and its photograph is labeled individually ("Square Foot Frequency") and positioned on the transect as noted on the form "Photo Trend Sample - 1 sq. ft." Place the 1-ft² plot at the first location, between 0 and 1 ft, with its identification card. Diagram the location of each plant species and label as shown in figures 75 and 76. Diagram basal area in bunchgrasses and area of rhizomatous or single-stemmed species when they occur within the square foot. The diagram is used for species identification and counting frequency, not for measurement of change. The stereo photograph is used to measure plant and soil change.

Under the plot diagram, circle soil surface items in the plot: "B" is bare ground (> 50 percent ground cover), "G" is gravel (> 50 percent ground cover of stones 1/8- to 3/4-in diameter), "R" is rock (> 3/4 in), "L" is litter (> 50 percent ground cover), and "C" is cryptogamic crust (> 50 percent ground cover).

Identify each square foot plot with the "Square Ft Frequency" form (app. B). It labels each 1-ft² plot and its photograph (figs. 75 and 76). One sheet is designed for use with all 20 plots on a transect. Try to print the necessary information in letters similar in size to those on the form. This will ensure readability in photographs. For plot 1, circle number 1, place form on ground next to the tape and adjacent to the square-foot plot. Place the plot frame at footmarks 1 and 2 as noted on the form. With a stereo adapter attached to the camera, hold the camera at eye level directly above the plot and expose for both the square-foot plot and the photo identification paper (fig. 75). For plot 2, cross out number 1 and circle number 2 (fig. 75). Place the plot frame at foot marks 5 and 6 as noted on the form. For plot 3, cross out number 2 and circle 3 (fig. 76) and place at foot marks 10 and 11. Repeat for all 20 plots. Use a new sheet for each transect.

Caution: Expose for both the photo identification paper and the plot. Generally, paper will reflect more light than vegetation and soil; the paper therefore should be slightly overexposed while soil and vegetation are slightly underexposed. Acceptable paper exposure is essential to read the printing in each plot photo. Medium blue paper, not office blue color, may be attained at most office supply stores.

In addition, from plot number 1, record shrub and tree (under 6 ft tall) canopy cover intercept by species above the transect tape between the start of one plot and the start of the next. Record beginning and ending foot marks and number of feet between intercepts. For example, in figure 76, plot 3 starting at 10 ft had a shrub intercept from 12 to 15 ft between it and plot 4, for a total of 3-ft crown intercept. Plot 5 starting at 20 ft had a shrub intercept from 22 to 23 ft between it and plot 6, for a total of 1 ft.

Another important source of supplemental information, particularly in the Pacific Northwest where many range types are forested, is the effect of tree cover. Cover must be sampled on all forested ranges. It is discussed as an additional transect sample in the "Tree Cover Sampling" section, below.

Summarize Data

After all 20 plots have been photographed and diagrammed, the transect is summarized on the last page of the "Photo Trend Sample - 1 sq. ft." form (fig. 77). The left side documents frequency and line intercept by species as well as by soil surface items. List all species found on the transect. Sometimes a shrub or tree species will be rooted in a plot for frequency and also will be recorded for crown intercept. Record the shrub or tree species in both cases. For frequency, count the number of plots in which the species occurred and record. For intercept, total the number of feet for each species and record (fig. 77).

The same procedure is followed at the bottom of the species listing for bare ground, gravel pavement, rock, litter, and cryptogams. Determine the number of plots in which each of these items occurred (fig. 77). Bare soil occurred in 18 sample plots, gravel pavement in 15, rock in 2, litter in 15, and cryptogams in only 8 plots.

The rest of the "Photo Trend Sample - 1 sq. ft." form is devoted to supplemental information (fig. 77). At the bottom left, record the two or three species sustaining the greatest utilization regardless of whether they are decreasers or not. The objective is to document how much utilization occurred for which species, not to estimate "proper use."

On the lower right side of figure 77, briefly describe any activities that occurred since the last transect reading. Provision is made for logging disturbance, fire, revegetation, insects, wildlife effects, and other.

Evaluate recent climatic conditions (fig. 77). Circle whether temperature was hotter, about average, or colder for this growing season (when the sampling was done), last year, two years ago, three years ago, and four years ago. Do the same for precipitation falling between January 1 and July 1: Was it above average, about average, or below average? This information should be available from local weather stations. Precipitation in the mountains can differ considerably from local stations, and no attempt is made to quantify differences.

Estimate whether apparent range condition is good, fair, poor, or very poor. These are range management terms equivalent to ecological definitions of potential natural vegetation (PNV), late seral, mid seral and early seral. PNV is the stable, native plant community that will become established after succession following disturbance. In much of the Pacific Northwest, livestock forage rating guides can be used to determine range condition. For areas without livestock forage rating guides, estimate range condition to the best of your ability.

Next, estimate apparent range trend. If you have a strong feeling that range trend is down, say so; if you have a strong feeling the trend is up, say so; if you are not sure about trend, say that also.

Space is provided for other comments. Whenever possible, make these additional comments in the field while you are looking at the transect.

If the site is forested, add the "Tree Cover Sampling" transect to this file.

Figure 80—Back of the "Range Trend Rereadings" form providing for data analysis by use of rating guides for livestock forage (range condition guides). The remaining transect summary data from figure 77 may also be added by date.

Range Trend Analysis

Data obtained by square-foot frequency are summarized for trend analysis in the filing system form "Range Trend Rereadings" (fig. 79). The form is designed for a series of up to 10 transect readings that may be compared side by side. The columns under "Averages by Year" require the year of reading to be entered at the top. The form in appendix B is printed front and back corresponding to figures 79 and 80.

Figure 79 is the front of the form. Circle which sampling system was used, "20 plots 1 sq. ft." in this case. Enter the information on area, allotment, and cluster number and circle the transect number. Enter the date of reading at the top of the "Averages by Year" column. Figure 79 shows three hypothetical transect readings: 1957, 1982, and 1997. The data in figure 79 refer to the 1997 reading.

If tree cover was sampled (trees over 6 ft tall), enter the total number of feet of intersect by species and total. Then enter the total number of feet of intercept by shrub species and total. Shrub species intercept is summarized on the last page of the form "Photo Trend Sample - 1 sq. ft." (fig. 77), a total of 7 ft.

The next data set (fig. 79) is for herbaceous species sampled by either 1-ft² or 1-m² or nested frequency. The data are summarized on the last page of the form "Photo Trend Sample - 1 sq. ft." (fig. 77). Circle the sample plot used ("1 sq. ft."). Enter the number of plots in which each species was rooted. Maximum number of plots for 1 ft² is 20 and 9 ft² or 1 m² has five plots. Nested frequency uses a different value. It is the total value of all five transects (100 plots) by species. See the "Nested Frequency Transect" section, below, for details.

Figure 80 shows the back of the form, which summarizes additional information and data. Enter data by date in the column "Averages by Year." If a range condition guide (or livestock forage rating guide) is available, list it and its date. In this case, an old bunchgrass guide of 1951 was used for the 1957 reading, which rated P (poor condition). A 1983 guide for big sagebrush (ARTR, *Artemisia tridentata* Nutt.) was used to estimate range condition for all three years. The 1983 guide showed data for 1951 rated F (fair) condition instead of poor.

These range condition guides list species by their reaction to livestock grazing: *decreasers* decrease under heavy use; *palatable increasers* are less palatable and tend to increase with heavy use. However, if heavy use continues, these species also decrease. *Unpalatable increasers* are species that livestock do not like to eat, and they tend to increase. *Invaders* are species generally not found on rangeland in good condition.

Data are summarized by the above categories of plant species (fig. 80). Total the number of plots by species in each category and enter. For example, AGSP (*Agropyron spicatum* vis. *Pseudoroegneria spicata* (Pursh) A. Love, bluebunch wheatgrass) is the only decreaser, so its data are entered (5 plots). Palatable increasers are POSA3 (*Poa secunda* J. Presl, Sandberg's bluegrass), SIHY (*Sitanion hystrix* (Nutt.) J.G. Sm., squirreltail), STOC (*Stipa occidentalis* Thurb. Ex S. Wats., needlegrass), and BASA (*Balsamorhiza sagittata* (Pursh) Nutt.,

arrowleaf balsamroot), so their data are summarized and entered in "palatable increasers" (18 plots). LOMAT (*Lomatium* species) and PHLOX (*Phlox* species) are considered unpalatable increasers and are entered as such (2 plots).

The next section of figure 80 deals with soil surface conditions. "Vegetation - (root crown)" is the number of plots in which a root crown of a bunchgrass is present. In 1997, 17 plots had a root crown and 3 had no vegetation rooted in them. Single stem plants, like many forbs, do not contribute directly to soil surface protection. This information is taken from the stereophotographs as is the frequency of bare ground, gravel, rock, litter, and cryptogams. The latter five items are summarized at the bottom left of the "Photo Trend Sample - 1 sq. ft." form (fig. 77). The section on "% Utilization by species" provides space to enter stubble height or other means to estimate utilization by species as taken from the "Photo Trend Sample" form, lower left. In this enclosure, there was no utilization. If there was use, estimate the season of use, as spring (spr), summer (sum), fall (fall), or winter (wint).

Climate information is listed in the next section for the current and preceding three years, which has been summarized in the lower right of the form, "Photo Trend Sample - 1 sq. ft." (fig. 77). Finally, copy the estimates of apparent range condition and trend from the "Photo Trend Sample." Abbreviations are G = good, F = fair, P = poor, and VP = is very poor, a condition where decreasers are absent and livestock management is no longer a feasible means for attaining an upward trend to good condition. Trend abbreviations are U = upward trend, S = static or no trend, and D = downward trend.

Trend Interpretation

Interpretation of trend is accomplished by comparison of data in the columns. Data for 1997 were measured; those for 1982 and 1957 were constructed. A current, soundly developed livestock forage rating guide (range condition guide) is a major aid in trend interpretation. Statistical analysis is not possible on this kind of data. No trend, or stable status, is indicated by little change in either vegetation or soil surface data.

Upward trend, or successional change to good condition (potential natural vegetation: PNV), is generally indicated by increased decreasers, and often palatable increasers, accompanied by a decrease in unpalatable increasers. If earlier condition was below fair, there should be improvement of soil surface conditions, such as litter and cryptogamic crust, with less bare soil. Seldom will rock or gravel change in an upward trend. Consult the livestock forage rating guide (range condition guide) for data characterizing the PNC soil surface status

A downward trend, or successional change to poorer condition (earlier seral status), is characterized by reduction in decreasers, increase in palatable increasers initially in fair and good condition (late and PNV seral status), and then their decrease as seral status approaches very poor condition (early seral). Soil surface data also should change with decreases in vegetation, litter, and cryptogams and increases in bare soil and possibly gravel.

Figure 81—Nested frequency sampling frame with four plot sizes and its carrying case. Plot size 4 is 5 by 5 cm, size 3 is 25 by 25 cm, size 2 is 25 by 50 cm, and size 1 is 50 by 50 cm. Plant species rooted within each of the plot sizes are assigned the plot size value. The ends of each prong are sharpened for use as point samples of soil surface conditions (short arrows). The frame case has a strap for easy handling.

Poor and very poor condition classes (early and mid seral ecological status) pose two important questions: (1) Has vegetation passed a threshold whereby it may not be able to regain its PNV composition and density of species? An example is a cheatgrass-dominated stand where decreasers are absent and only a few palatable increasers are present. Adjustment in livestock management is no longer feasible to attain an upward trend. (2) Has the soil been damaged sufficiently that it has passed a threshold and no longer can support the historic PNV community? Such threshold changes are indicated by erosion of the A-horizon, increase in gravel as a result of erosion, and severe compaction. A well-developed livestock forage rating guide contains parameters on PNV status of bare ground, gravel pavement, rock, and A-horizon characteristics that may be compared with current soil conditions. It should specify criteria when a soil threshold has been crossed.

Nested Frequency Transect

Nested frequency employs a sample frame with four nested plot sizes. It documents change in species frequency along five 100-ft transects of 20 plots each. Statistical analysis suggests significant change in frequency at the 80-percent level of probability.

Concept

Frequency is defined as the number of times a species occurs (is rooted) in a given number of plots and considers only whether species are present or absent. It is an objective and repeatable means of collecting data to evaluate change.

The nested frequency concept involves sampling vegetation with four various sized plots nested within a frame (fig. 81). The overall frame is 50 by 50 cm with smaller subplots of 25 by 50 cm (50 percent of the large plot area), 25 by 25 cm (25 percent of the large plot area), and 5 by 5 cm (1 percent of the large plot area). The assumption is made that a species rooted within the 5- by 5-cm subplot also occurs in the 25- by 25-cm subplot, the 25- by 50-cm subplot and in the 50- by 50-cm subplot. Similarly, a species rooted in the 25- by 25-cm subplot occurs in the larger subplots. Therefore, once a species is recorded in a subplot, it is **not** recorded if found in a larger subplot.

Samples are taken along five randomly selected transect lines confined to a single ecological type (range site). The data collected are a function of plot size, which is related to density and distribution of the vegetation. These data serve as a basis for determining trend and can be evaluated by applying statistical procedures. Statistical analysis requires use of 100 plot frames or 400 total plots. Twenty plot frames on each of five transects yield 100 plot frames.

Ground cover measurements are obtained by sampling soil surface items under pointed ends of four prongs of the nested frequency frame (fig. 81). Twenty sample frames on five transects will yield 400 sample points. Items recorded are vegetation (root crown), bare soil, gravel (1/8- to 3/4-in diameter), rock (>3/4-in), litter, and cryptogams.

When trees or shrubs occur on the transect, their canopy intercept above the transect is recorded.

It is recognized that the nested plot has apparent replication. A plant occurring in the 5- by 5-cm plot also occurs in the 25- by 25-cm plot, the 25- by 50-cm plot, and the 50- by 50-cm plot. As this is a question of statistical bias, two things overcome the possible sampling error. One is that each frame is not an independent sample; therefore, only one degree of freedom is used. Secondly, empirical analysis indicates that if a site is adequately sampled, in this case 400 nested plot samples (100 plot frames), the final result is highly similar whether all plots are randomly tested or if a nested plot (with apparent replication) is used.

Plants rooted within each of the four plots in the frame are recorded by plot size. The 5- by 5-cm plot is assigned the value of 4 (fig. 81), the 25- by 25-cm plot the value of 3, 25- by 50-cm plot a 2, and the 50- by 50-cm plot a 1. These values are then assigned by species and recorded on the filing system form, "Nested Frequency Transect Data" (fig. 86, discussed below).

	05	04	95	48	06	74	69	00	75	67
	42	24	52	32	45					

Equipment

The following equipment is required for nested frequency sampling:

1. Camera or cameras with both color and black-and-white film, or digital camera
2. A nested frequency plot frame (app. C)
3. Forms from appendix B: "Cluster-Transect" for transect identification, and "Nested Frequency" for plot identification both printed on medium blue paper, and data and photo mounting form "Photo Trend Sample - Nested Frequency" and "Photo Trend Sample -Nested Frequency Summary" printed on medium yellow paper
4. Meter board (app. C)
5. Clipboard and support for holding the photo identification forms (app. C)
6. A compass and 100-ft steel tape with clamps or vice grips to clamp onto angle iron stakes
7. Fenceposts and angle iron stakes sufficient for the number of transects desired: 2 fenceposts and 3 angle iron stakes per transect and a pounder
8. Metal detector for locating transect stakes

Technique

Each of the five transects is defined as a randomly selected line along which data are collected. A minimum of five transects are established at five randomly selected compass directions radiating from a central point whenever site conditions are suitable.

Select compass headings in 10-degree increments between 0 and 35 from table 2. If site conditions require placement in a line, distances between transects should be randomly chosen. The example below illustrates transect placement around a central witness location by using the first five values in table 2 that are between 0 and 35 (from 0 degrees; that is, 360 degrees to 350 degrees). Chose numbers less than 36 (360 degrees) and add a "0" to the value for compass bearing. For example, in the first row, "23" would be a compass bearing of 230 degrees for transect 1. Transect 2 would be 250 degrees, transect 3 is 10 degrees, transect 4 is 240 degrees, and transect 5 is 80 degrees. Select a different row for each new cluster of five transects.

Placement of the transects requires a witness site with direction (indicate whether magnetic or true) and measured distance to the central marker for five radiating transects or to transect number 1 (fig. 82). For radiating transects, measure out 5 ft from the central marker (fencepost) and start the transect as discussed under "Transect Layout" in the "Transect Photo Sampling" section above. Record direction determined above (magnetic or true) and distance to the three angle iron stakes. If transects are in a line, record direction and measured distance between the 100- and 0-ft ends of each transect (fig. 74).

Diagram the transect layout on the filing system form (fig. 82), and fill out information on the form. Remember to circle "Nested Freq." on the top line of the form. Note the transect numbers at their 0-ft ends.

Each transect photo is identified by the filing system form shown in figures 83 and 85. The photo identification form should be printed on medium blue paper for use in the photographs. Fill in the date (97/3/22), circle either "0" or "100" (fig. 83 is 0, fig. 85 is 100) to indicate which end of the transect is being photographed, note area (CRNG), allotment (Madras), and cluster number (3), and circle the transect number (1).

Place the nested frequency plot frame uphill on the left of the transect tape as viewed toward the 100-ft end. Locate the 5- by 5-cm plot against the tape, open end of the frame toward the 100-ft end. Figures 83 and 84 show, under the plot diagram, foot marks on the tape where each plot frame is placed. Print this form on medium yellow paper to reduce glare because it is used to record data.

Place the nested plot frame at the first location, between 0 and 1.6 ft. The form "Nested Frequency" (app. B) shown in figures 83 and 84 identifies each plot frame. It should be printed on medium blue paper to reduce overexposure in the Sun. For photo plot 1, circle number 1 and place on the ground at the open end of the plot. For plot 2, cross out number 1 and circle number 2 (fig. 83). Repeat for all 20 plots (fig. 84).

List all species in each frame and diagram their locations (figs. 83 and 84). A plant is considered rooted within the plot if any portion of the stem or root crown is contained therein. For mat-forming species, any portion of the crown extending into the plot will constitute presence of that plant.

Hiway exclosure

Figure 85—Last page of the filing system form "Photo Trend Sample - Nested Frequency." Notice that data are not summarized on this form. Instead, they are summarized for each transect on the filing system form, "Nested Frequency Transect Data" (figs. 86 and 87), and all five transects are summarized on another form, "Nested Frequency Cluster Summary" (figs. 88 and 89). Fill in activities, climate, and comments as appropriate.

Next, record point sampling by noting what is under the pointed end of the four prongs (figs. 83 and 84). Use the following abbreviations: V = vegetation (plant root crown), B = bare soil, G = gravel (stones 1/8- to 3/4-in diameter), R = rock (> 3/4 in), L = litter, and C = cryptogams. These are point samples.

After photographing and diagramming a plot, determine shrub or tree (under 6 ft) intercept along the line from the start of one plot to start of the next. For example, figure 84 between plot numbers 3 and 4 (between foot marks 10.0 ft and 15.0 ft), ARTR (big sagebrush) intersected the line from foot marks 12 to 15 for 3 ft of intercept.

Proceed down the transect with photographs and diagrams of each plot frame. Complete the last page of the form "Photo Trend Sample - Nested Frequency" (fig. 85).

Another important source of supplemental information is the effect of tree cover. Cover should be sampled on all forested ranges. It is discussed below in the "Tree Cover Sampling" section.

Summarize Data

Transect summary—Using diagrams for each sample on the form, "Photo Trend Sample - Nested Frequency" (figs. 83 and 84), summarize them on the filing system form, "Nested Frequency Transect Data" (figs. 86 and 87). Fill in information at the top for unit, area, cluster, and transect. This form is printed front and back. The table lists "Sample Number" across the top. These correspond to the sample numbers shown on figures 83 and 84. Species are listed down the left side.

Using "Nested Frequency Transect Data" (fig. 86), start with sample 1 of the transect (fig. 83) and evaluate the smallest subplot (rated 4 in fig. 81), record species rooted within it, and assign the frequency value of 4 (no species in sample 1). Next record species rooted within the next largest subplot (rated 3 in fig. 81) and assign a frequency value of 3. POSA3 is recorded at 3. Continue with the next largest plot (25 by 50 cm) rating species a 2 (none in sample 1). Do **not** record a species rooted within a smaller plot. Finally, record species only in the whole plot frame (50 by 50 cm) with a 1 (none in sample 1).

Continue to record the frequency value in each sample by species (fig. 86). Total the value for each species on the right. These totals will be entered in the form, "Nested Frequency Cluster Summary" (figs. 88 and 89). The maximum total would be 80 if the same species occurred in every 5- by 5-cm plot rating 4. Species that do not fall in a plot of the frame are not given a value; that is, ARTR and BASA in figure 86.

Next summarize point sampling at the bottom of figure 86. Dot tally the occurrence of each of the six items from abbreviations at the ends of the four frame prongs (figs. 83 and 84). Sum the dot tallies in the "Totals" space. Next add the totals row for a grand total, which must equal 80 because there are 80 points in the 20 samples.

NEXT SHEET FOR LINE INTERCEPT OF SHRUBS AND TREES

Figure 86—Filing system form “Nested Frequency Transect Data,” where frequency values by species and point sampling on the plot frame prongs are recorded. Starting with plot frame 1 (sample number 1), list the frequency value for each species in the “Sample Number” column. POSA3 rated a “3” (fig. 83). Next, add up the 20 frequency values and enter in the “Total Value” column. POSA3 added to 56. Transfer these values to the “Nested Frequency Cluster Summary” form (fig. 88). Then, dot tally in “Point Sampling” the items at each of the four prong points. Plot 1 had one litter (L), two bare soil (B), and one cryptogam (C). Add the dot tallies in each column by item. The sum of these “Totals” tallies should be 80. The sum of each item is then transferred to the “Nested Frequency Cluster Summary (continued)” form (fig. 89).

OVER FOR ADDITIONAL DATA

Figure 90—The filing system form “Range Trend Rereadings” where transect data are entered each time the cluster is read. Circle the sampling system on the first line (“100 plots Nest. Frequ.”). Enter the cluster identification information. Notice that “Transect 1 2 3 4 5” are all circled. Enter the line intercept for shrubs and trees from each “Nested Frequency Cluster Summary (Continued)” (fig. 89) by year. Circle “nested frequ. value” and enter the sum of frequency values by year from figure 88. These values, by species, will be tested for significant change by using table 3. See text for details.

Figure 91—Second page of the "Range Trend Rereadings (Continued)" form where data are interpreted for change in vegetation and soil surface characteristics. If a range condition guide (livestock forage rating guide) applies to the monitoring area, list it and its date. Then rate the condition of each rereading. Next list the frequency values for decreaseers, palatable increaseers, unpalatable increaseers, and invaders. There is no maximum value because species are lumped together and may total more than 400. See text for details.

^a Using 100 nested frequency plot frames, the table shows a significant change in frequency value at the 80-percent probability level. Enter the table at "Initial value" with the *previous* frequency value for the 5 transects(100 plot frames). Compare the *previous* value with the *current* value to determine whether a significant change has occurred. A change is significant if the *current* value is smaller than the "Less than" value or greater than the "More than" value.

Finally, if shrubs and trees were intercepted, record the number of feet of intercept on the form, "Nested Frequency Transect Data (Continued)" (fig. 87). Total the number of feet and determine the percentage cover. For ARTR, 6 ft of intercept in 100 ft of line is 6 percent. If a tree or shrub was not intersected, there will be no data for it.

Cluster summary—Once the transect has been summarized, transfer data to the filing system form, "Nested Frequency Cluster Summary" (fig. 88). Fill in the required information at the top. List species down the left side and enter their frequency values by transect. Add the species values for a "Total Value." These total values are transferred to the "Range Trend Rereadings" summary to test for significant change in species (fig. 90). The maximum value possible would be 400 if the same species occurred in all 5- by 5-cm plots on all transects.

Next, transfer the line intercept data for each transect to the "Nested Frequency Cluster Summary (Continued)" form and total (fig. 89). A total of 35 ft of ARTR was intersected in 500 ft of transect for 7 percent cover. Transfer the intercept in feet to the "Range Trend Rereadings" form (fig. 91).

Finally, transfer the point sampling data by transect to the "Nested Frequency Cluster Summary (Continued)" form (fig. 89). These data must be added in two directions. Each transect column must add up to 80. Then add each item by row for their total hits. Add the "Total Hits" column, which must add to 400. Finally, determine the percentage of each item (hits/400). Transfer total hits to the form, "Range Trend Rereadings (Continued)" (fig. 91).

If the site is forested, tree canopy cover must be determined, a topic discussed in the "Tree Cover Sampling" section, below

Trend Interpretation

Interpretation of trend in species frequency values is facilitated by table 3, used in conjunction with the "Range Trend Rereadings" summary form (fig. 90). Interpretation is illustrated with measured data for 1997 and constructed data for 1957 and 1982. For example, AGSP, a decreaser, is a key species used to indicate trend. In 1982, its total frequency value was 92 and in 1997 it was 114. The previous value of 92 is located in table 3 in the "Initial value" column, falling between 90 and 95. Then the current value of 114 is compared to the values in the "More than" column opposite 90 and 95. These table values are 102 and 107. Because 114 exceeds the values, there is an 80 percent probability that a significant upward trend in AGSP frequency has occurred.

Downward trend is a reverse of this procedure. The 1982 total frequency value for POSA3 of 288 was the initial value and the value for 1997 of 274 is the current value (fig. 90). In table 3 in the "Initial value" column, find 288 and read 266 as the "Less than" value. The current value of 274 is not less than 266 and the downward change in POSA frequency therefore is not significant.

LOMAT, an unpalatable increaser, on the other hand, did show a significant decrease between 1957 and 1997. The initial value of 43 (fig. 90) is found in the "Initial value" column with a "Less than" value of about 33. The 1997 frequency value of 29 is less than 33, thereby suggesting an 80-percent significant probability of a reduction in frequency.

One could conclude that an increase in AGSP, a decreaser, and a decrease in LOMAT, an unpalatable increaser, indicate an upward trend in range condition. There is no statistical test for line intercept or point sampling data. Interpretation would suggest little change in ARTR cover. A decrease in bare soil and an increase in cryptogams, from 1957 to 1997 (fig. 91), suggested by table 3, would tend to support an upward trend interpretation.

In the upper left of the "Range Trend Rereadings (Continued)" (fig. 91) form under the "Elements" column, provision is made for use of range condition guides (live-stock forage rating guides). List the guide name and date if one is applicable to the ecological type. The guides group plant species into four categories. Decreasers are

species that are most palatable and decrease in frequency with heavy livestock use. Palatable increasers are species that are eaten but are less palatable than decreasers. They tend to increase in frequency or percentage of composition as decreasers decline. If heavy grazing continues, these species also decline. Unpalatable increasers are species that livestock do not care to eat but are present in good range condition (potential natural community ecological status). Invaders are those species that generally do not occur in good condition; they invade the site after serious heavy grazing.

Add the frequency values of those species falling into each category. For example, AGSP is the only decreaser so its frequency value for 1997 is 114. Palatable increasers are POSA3, BASA, SIHY, and STOC, whose frequency values (fig. 90) add up to 287 ($274 + 2 + 9 + 2 = 287$). Unpalatable increasers are ARTR, LOMAT, and PHLOX whose frequency values add up to 42. There is no statistical test for significant change in these items. They are presented to aid interpretation.

Nine-Square-Foot (1-Square-Meter) Plot Transect

Nine-square-foot transects are designed to enhance the three-step sampling system by increasing the number of ground view photographs from two to five. Reppert and Francis (1973), in their analysis of the three-step method, found photographs to be the most useful part of the method and could be used to test and validate the transect data.

Concept

The 9-ft² (1-m²) plot system is derived directly from the three-step concept of a general transect photograph plus a photo of a 3-ft square at each end of the transect. This system adds three more 9-ft² (1-m²) plots at the 25-, 50-, and 75-ft locations on the transect. Photographs are taken of the plot frame at an oblique angle from eye level. There are no plot measurements involved, but line intercept of woody species is provided. A grid may be imposed on the plot frame by physically connecting marks on the frame, but interpretation is difficult owing to the oblique angle.

The 9-ft² (1-m²) plot is not a sample of frequency because five plots are too few and 9 ft² is too large. In many cases, two or more species will occur at 100-percent frequency. A person cannot determine whether plants were spaced at 2 ft 10 in in distance (which would mean 100-percent frequency) or at 10 in in distance (which also would result in 100-percent frequency). The difference between 10 in and 2 ft 10 in can be important in evaluating range trend. Five plots of 9-ft² do provide, however, a repeatable view of vegetation and soil surface conditions for comparison between photos taken over time, a subjective means for interpreting trend.

Equipment

The following equipment is required for 9-ft² (1-m²) sampling:

1. Camera or cameras with both color and black-and-white film, or digital camera
2. A 9-ft² (1-m²) plot frame (app. C)
3. Forms from appendix B are for transect identification, "Cluster – Transect," and for plot identification "9 sq. feet - 1 sq. meter" printed on medium blue paper; and data and photo-mounting form, "Photo Trend Sample – 9 sq. ft. (1 sq. m)," printed on medium yellow paper
4. Meter board (app. C)

5. Clipboard and support for holding the photo identification forms (app. C)
6. Compass and a 100-ft steel tape with clamps or vice grips to clamp onto angle iron stakes
7. Fenceposts and angle iron stakes sufficient for the number of transects desired: 2 fence posts and 3 angle iron stakes per transect, and a pounder
8. Metal detector for locating transect stakes

Technique

Establish the transects and map them on the filing system form, "Sampling Site Description and Location" (fig. 92). Fill out information on the form and circle "1 sq. m" on the top line. If transects fall in a line, continue the map on the back of the form (fig. 74).

General photographs from the 0- and 100-ft ends of the tape are required (figs. 93 and 95). Remember to circle "0" for the front photo and cross it out and circle "100" for the end photo.

The 9-ft² (1-m²) plot transect is different in several respects from the 1-ft² and nested frequency transects:

1. Plot photographs are taken from an oblique angle rather than overhead
2. The picture is taken down the transect line
3. The transect line bisects the center of the plot (figs. 93 and 94)
4. The photograph of the last plot is taken from a different direction. Photo plot 1 is taken with camera over the 0-ft stake and the plot at 3.5 to 6.5 ft, whereas the last plot at 96.5 to 93.5 ft is taken with the camera over the 100-ft end and aiming back down the transect to the plot

Place the plots, on center, down the transect. Figures 93 and 94 illustrate the foot marks on the transect where each plot is located. Place a 9-ft² (1-m²) plot between the 3.5- and 6.5-ft marks (fig. 93). Roughly diagram the location of each species and label. Circle soil surface items listed under the plot diagram: B = bare soil (> 50 percent of ground cover), G = gravel (> 50 percent cover of stones 1/8 to 3/4 in), R = rock (> 3/4 in), L = litter (> 50 percent of ground cover), and C=cryptogams (> 50 percent of ground cover).

Fill in photo identification form "9 square feet-1 square meter," circle photo 1 and place at a far edge of the plot (fig. 93). Handhold the camera over the 0-ft stake (see note in fig. 93 under the photograph), make sure the photo identification sheet is visible, and take the photo.

Move to the next plot location at 25 ft (fig. 94). Determine canopy intercept along the line for trees less than 6 ft tall and shrubs from the start of plot 1 (0.0 ft) to the start of plot 2 (25.0 ft). A single species may have more than one intercept if more than one individual crosses the transect between 0 and 25 ft (fig. 93).

At plot 2, repeat diagrams. Camera location is at foot mark 21.5 (3.5 ft away from the plot) as shown in figure 94 under the photograph. On photo identification form, "9 square feet - 1 square meter," cross out "1," circle "2," and photograph.

COMMENTS

A hiway enclosure

Estimated Utilization

Species % Use

Figure 95—Summary sheet of the "Photo Trend Sample - 9 sq. ft. (1 sq. m)" form with the 100-ft transect photograph. Frequency of occurrence by species is on the left. Under that is frequency of soil surface items. Fill out appropriate information on the right.

Do the same for plots 3 and 4.

Plot 5 is different. It is photographed in the opposite direction from the others, back down the transect (see number 4, above).

Summarize Data

After sampling, fill in the summary on the last page of form, "Photo Trend Sample - 9 sq. ft. (1 sq. m)" (fig. 95). It is the same summary sheet used with the 1-ft² plots, and the procedure is identical. If the site is forested, tree crown cover must be sampled as discussed below.

Trend Interpretation

Transfer summary data from the last page of the form, "Photo Trend Sample - 9 sq. ft. (1 sq. m)" (fig. 95) to the "Range Trend Rereadings" form (figs. 96 and 97). Fill out the form information and circle "5 plots 9 sq. ft. (1 sq. m)" on the top line. Enter the transect intercept data by date of rereading. Then enter the frequency data by date of rereading (fig. 96). Data were measured for 1997 and constructed for 1957 and 1982.

On the second page (fig. 97), summarize by date and frequency by decreaser, palatable increaser, unpalatable increaser, and invader. Do not add up the frequency ratings from the first page (fig. 96) because frequency of these large plots is not additive. Instead, return to the data forms (figs. 93 and 94) and count the number of plots by species. Often two species in a category, such as unpalatable increasers, will occur in the same plot. The total frequency for unpalatable increasers from figure 96 is 4 but the frequency for the category had a frequency of only 3 (LOMAT, PHLOX, ARTR).

Transfer the soil surface items. Vegetation is any plant root crown, so a frequency of 5 for a species would be a 5 for vegetation. Transfer utilization and climate information. Finally, transfer the estimated range condition and trend information.

Interpretation of change is based on professional judgment and interpretation of photos.

Tree Cover Sample

Tree cover has direct influences on ground vegetation by casting shade. Trend in density and composition of species is often as much influenced by this shade as by grazing or light disturbance. Any transect placed in a forest setting should have tree cover sampled.

Concept

Tree canopy cover significantly influences density and composition of ground vegetation (shrubs and herbs). The effect is so important that documentation of tree cover on forest land transects is strongly recommended. Tree canopies are photographed by using a camera leveling board to assure vertical orientation of the camera (fig. 98).

On a 100-ft transect used for square-foot, nested-frequency, or 9-ft² (1-m²) sampling, photograph tree cover at the 0-, 25-, 50-, 75-, and 100-ft locations. Overhead photos also may be taken with topic photography utilizing a single overhead photo (fig. 52). At 40-percent canopy cover using a 50-mm lens, trees taller than 70 ft will

appear in adjacent pictures providing a continuous 100-ft transect of tree cover. If a 35-mm lens is used, trees over 50 ft tall will provide a continuous strip. Whatever focal length is used to begin, the **same focal length** must be used for subsequent photos. Long axis of the camera should be across the transect.

Equipment

The following equipment is required for sampling tree cover:

1. Camera or cameras with both color and black-and-white film, or digital camera
2. A camera leveling board (app. C)
3. Form from appendix B for data and photo mounting: "Photo Trend Sampling - Tree Cover"
4. Meter board (app. C) to set the leveling board and camera on
5. A compass and 100-ft steel tape with clamps or vice grips to clamp onto angle iron stakes used for ground vegetation sampling
6. Fenceposts and angle iron stakes sufficient for the number of transects desired: 2 fenceposts and 3 angle iron stakes per transect and pounder (these are on the equipment list for ground vegetation sampling system)
7. Metal detector for locating transect stakes

Technique

On the 100-ft transect used for square feet, nested frequency, or 9-ft² sampling, photograph tree cover at the 0-, 25-, 50-, 75-, and 100-ft marks. Position the meter board at each of the foot marks, place the camera leveling board on top of the meter board, and set the camera on the leveling board with the long axis perpendicular to the transect and the viewfinder toward the 0-ft mark (fig. 98).

Move the meter board sideways to level the camera board cross-transect. Then level the camera board down-transect, bend down to take your head out of the picture, and photograph (fig. 98).

Important criteria—There is neither a size control (meter board) nor photo identification sheet in these pictures. Four procedures, therefore, **must** be followed:

1. The same focal length lens must be used for all subsequent photographs so images can be compared. Note the effects of focal length in figures 6 and 7.
2. The camera must be the same height aboveground. Use the meter board for consistent heights. Figures 2 and 3 illustrate the effect of change in distance using the **same focal length** lens.
3. Make sure the camera is oriented perpendicular to the transect with the viewfinder toward the 0-ft mark (fig. 98). Remember this by viewing the transect through the camera, and then rotating it 90 degrees upward to view the canopy. This camera orientation helps with placement of photos on the form. There is no "right side up" on these photos. Their orientation can be determined only by the exposure numbers at the bottom of the film.
4. Write down the film exposure number and the cluster and transect data so that negatives can be identified and picture orientation determined.

Figure 98—Tree canopy cover photography system. A meter board is placed crosswise (perpendicular) to the transect at foot marks 0, 25, 50, 75, and 100. Hold camera level board on top of the meter board and place the camera on the level board. First center the cross-transect level by moving the meter board sideways. Then tilt the camera level board so the down-transect-level is centered, move your head out of the camera view, and photograph.

Summarize Data

Attach crown cover photos to the filing system form, "Photo Trend Sampling - Tree Cover" (figs. 99 and 100). Fill out information on the top two lines. Roughly diagram canopy outlines and label by species for identification. Then proceed as follows to determine canopy cover on each photo (figs. 99 and 100):

1. Print on clear plastic five copies of the grid analysis outline form (fig. 54), one for each photo. Tape along one edge over a photo and enter information for the photo (fig. 101). Outline the tree canopies carefully and identify by letter or number.
2. Print (without size adjustment on white paper) a copy of the analysis grid for shrub analysis (grid with meter boards at each edge) from appendix B. Remove the outline overlay from the photo and tape onto the grid. Orient the outline overlay on the bottom line of the grid and next to the left meter board but one grid line to the right (fig. 101). The top and right edges of the outline probably will fall between grid lines.
3. Determine the total number of grid intersects on the picture. Remember to count the left and bottom grid lines to determine total number. In figure 101, there are 26 grid lines across and 17 up for a total of 442 intersects.

$$SD = 22.67$$

$$SE = 10.18$$

$$CI_5 = 28.3$$

Figure 100—Second page of the "Photo Trend Sampling - Tree Cover" form with the cover summary. In this case, statistical analysis results were added: SD = standard deviation, SE = standard error, and CI_5 = the confidence interval at the 5-percent level of probability.

Figure 101—Determination of tree canopy cover using grid intersect. The grid intersect outline form printed on clear plastic is overlaid on photo **A** and tree canopies outlined, here for the 25-ft photo (fig. 99). Then in **B**, the outline is placed on the shrub analysis grid (with meter boards at each side) and printed on paper. Intersects within each tree canopy outline are counted (131) and divided by the total number of intersects within the photo (442, or 17×26) for 30-percent canopy cover.

4. Decide if tree canopy or open space will be counted. To ease counting, I prefer to count the item of least coverage: open space in the 0-ft picture of figure 99 and tree cover in the 25-ft picture (fig. 99). Count grid intersects on the left edge and bottom of the photograph. When counting open space, subtract the grid intersects from the total to determine canopy cover. In figure 101, the number of grid intersects falling on the tree canopy is 131. Percentage of cover is $131 \div 442 = 29.6$, or 30-percent canopy cover.
5. For each photo, list canopy cover by species on the left of the filing system form, "Photo Trend Sampling Tree Cover," under the canopy diagram. Retain each outline as a permanent data form.
6. Add canopy cover for each photo, average, and enter in the summary shown in figure 100: a total of 330 divided by 5 is an average of 66-percent canopy cover.

Trend Interpretation

If there are five samples for statistical analysis of change, the mean of 66.0 will have a standard deviation of 22.7, a standard error of 10.2, and a confidence interval at the 0.05-percent probability level of 28.3 (fig. 100). The Student's T-test may be used to evaluate significant change in tree canopy cover between two data sets.

Usage Measured by Robel Pole

Stubble height of vegetation remaining after livestock grazing indicates animal preference for certain areas, may be used to adjust animal distribution, and suggests intensity of utilization. The Robel pole system documents this stubble height.

Concept

The basic concept is to measure stubble height, or ungrazed herbaceous height, by using a pole marked in inches and photographing it (a "visual observation") from a specific distance and height aboveground. Robel and others (1970) discuss the mathematics and test results. Guenther (1998) used the same concept to estimate annual grass herbage production in California. He uses two views: one from 20 ft and another from 10 ft. A 0.96-ft² hoop is placed at the base of the pole for visual reference.

The pole is 2.5 in in diameter and marked in alternate black bands by inches (fig. 102). A 4-m-long line is attached at 1-m height on the Robel pole and connected to the top of a 1-m-tall line pole (app. C). The Robel pole is set at the sample location (station) while the line is stretched and a photograph taken (visual observation) from the top of the line pole (fig. 103). Landscape orientation seems to be better than portrait for depicting utilization, because the former broadens the view at the Robel pole.

The location of the Robel pole is termed a "station" from which two visual observations are made: one in the direction of the transect and a second 180 degrees backwards to the start of the transect.

These consistently used measurements, 4-m distance and 1-m height of camera (4-to-1 ratio), provide repeatable angles for documenting stubble height (Robel and others 1970).

Figure 102—Robel pole has two main parts: the Robel (measuring) pole (A) and the camera height pole (B). The Robel pole is 2.5 in diameter and the camera height pole 1.5 in so the latter will fit inside the Robel pole. “A” points to an eye where a 4-m long line is attached. The line is shown wrapped around the camera height pole in B. A tent peg with 2 m of line may be used to hold the Robel pole when one person is sampling. See appendix D for details.

Transects generally are not permanently located with fenceposts and steel stakes. A fencepost marking a sampling station may significantly alter domestic livestock use owing to its physical presence. If permanent transects are desired, they should be located with fenceposts identifying the transect start and end. They may be set at visual observation camera locations with the station located by a steel stake driven flush with the ground. A metal detector is needed for relocation (White’s Electronics, Inc. 1996).

Equipment

The following equipment is required for Robel pole transect sampling:

1. Camera or cameras with both color and black-and-white film, or digital camera
2. Robel pole with its 4-m line and a line pole (fig. 102, app. C)

Figure 103—Technique for photographing the Robel pole. In this case, the camera is held in the “portrait” or vertical position. I prefer the “landscape” or horizontal camera orientation (see fig. 106) because it covers a broader area of ground at the Robel pole. Spikes on the bottom of the Robel pole and line pole (fig. 102) are 1/4-in steel rod 6 in long, which are capable of holding both poles upright.

3. Forms from appendix B for transect identification, “Cluster – Transect,” and station identification, “Utilization - Robel Pole,” both printed on medium blue paper, and data and photo-mounting form, “Utilization - Robel Pole Sampling,” printed on medium yellow paper
4. Meter board (app. C)
5. Clipboard and support for holding photo identification sheet (app.C)

Technique

Site selection is a function of animal use and management objectives. For this illustration, a moist meadow in forested rangeland was selected because it is the most palatable kind of vegetation in the area and because it is adjacent to a water hole. Provide the usual two maps: one to locate the sampling area (fig. 104) and another to map the sampling transect (fig. 105). Draw a map on the filing system form, “Sampling Site Description and Location” and fill in necessary information.

1. Determine the number of transects and number of visual observation stations per transect. Then determine the direction of each transect and the interval between stations. All are influenced by two factors: homogeneity of vegetation and uniformity of animal use. Record and map transects on the filing system form, “Sampling Site Description and Location” (fig. 105). The filing system form, “Utilization - Robel Pole Sampling,” provides for 25 stations and 50 observations (fig. 106).

MAP

Figure 105—Filing system form "Sampling Site Description and Location" with information and transect location diagrammed. Remember to circle the sampling system, "Robel Pole," on the first line.

2. In this illustration, the meadow is small, oblong, and homogeneous. Only one transect is needed with 10 stations. The transect is oriented lengthwise and calls for a compass heading of 273 degrees magnetic and a total distance of 94 yd, which results in 8-yd intervals between stations (fig. 105).
3. Mark station 1 of the transect with the meter board. Place the camera location fencepost 10 m distant on the transect line. Fill out the transect photo identification form, circle the "0," place it at 5 m, and photograph the transect (fig. 106 A).
4. At the first station, fill out the photo identification form, "Utilization - Robel Pole Sampling," printed on medium blue paper; circle "1A," and place next to the Robel pole at the station (fig. 106 B). Extend the line its full 4 m along the transect toward the fencepost that locates the transect. Set the line pole on the transect line, and photograph the Robel pole with the bottom of the pole in the center of the photo (fig. 106B). Focus on the pole to assure the sharpest image.
5. Using the filing system form, "Utilization - Robel Pole Sampling," printed on medium yellow paper (fig. 106), fill in the first page. Then opposite "Visual Observation 1A" (station 1), record the stubble height, any comments, and the one to three species immediately in front of the pole that are being measured for stubble height. In this case, Kentucky bluegrass and analogue sedge are intermixed (fig. 106 B). Stubble is shown on the white "3" band with very little on the black "4" band. Record 3 for stubble height (3 in).
6. Next, move to the opposite side of station 1, 180 degrees, for visual observation 1B (fig. 106C). Pick up the line pole, turn the Robel pole and the photo identification paper around, cross out "1A" and circle "1B" on the identification paper, extend the line, and repeat the photography (fig. 106C). Record on the "Utilization - Robel Pole Sampling" form, in the "Visual Observation 1B" space, species being measured, the stubble height, and any comments. In this case, Kentucky bluegrass and California oatgrass are intermingled. Stubble is shown on the black "2" band and not on the white "3" band for a height of 2 in.
7. For the next station, determine direction and step off the required distance, in this case 8 yd. Forms in appendix B following the first page of "Utilization - Robel Pole Sampling" do not have visual observation (station) numbers, but a blank space instead (fig. 107). Print sufficient sheets for the number of stations. Then enter appropriate visual observation (station) numbers. Thus each station has its own page. Take photographs, data, and notes as discussed above (fig. 106).
8. Repeat for each station (figs. 107 and 108). At the end of the transect (fig. 108C), establish a fencepost 10 m beyond the last station. On the transect photo identification sheet, cross out the "0" and circle "100" to indicate the end of the transect. Photograph the transect looking toward the "0" end.

Figure 109—Filing system form "Utilization - Robel Pole Summary" with location information, stubble heights, and species taken from the transect data and photo-mounting form. Add the stubble heights in each column (37 and 38), total the columns (75), and determine the average ($75 \div 20 = 3.75$). The average stubble height is 3.75 in. Variability in stubble height may be calculated by determining the standard deviation (SD), standard error (SE), and the confidence interval at the 5-percent confidence level (CI₅). These have been entered on the form. The stubble height is 3.75 ± 0.66 in, at the 5-percent confidence level.

Summarize Data

Add each of the stubble height columns: visual observation A ("VO A") is 37 and "B" is 38; then add the column totals: $37 + 38 = 75$. Determine the average stubble height for 20 observations: $75 \div 20 = 3.75$. In this example, the standard deviation (SD) was 1.41, standard error of the estimate (SE) was 0.32, and the 5-percent confidence interval (CL_5) was 0.66, which were recorded on the form. These data also may be used to determine significant differences among transects by using the Student's t-test. In this case, the stubble height was 3.75 in ± 0.66 in at the 5-percent probability level.

Appendix B: Blank Forms for Photo Monitoring

This appendix contains forms for photo monitoring. To be of the most use, they need to be copied onto three paper colors or overhead projection clear plastic, depending on their use. Office forms are printed on standard white paper. Field forms are printed on either of two colors: blue paper to place in photographs to identify each photo or yellow paper to ease eye strain for field forms. Outline forms for grid analysis are printed on clear plastic. Grids and summary forms are printed on white paper. Paper colors I've found suitable for each form are shown in **bold**.

White paper is used for summary forms and for grids adjusted to size of the outline overlays.

Blue paper is Hammermill Brite Hue Blue® or Georgia Pacific Papers Hots Blue®, or equivalent, used in the actual photographs for identification. This shade of blue has proven to be least sensitive to changes in sunlight, from full sun to shade, and has the least tendency to "bleach out" in full sun.

Yellow paper is Champion Goldenrod® or Hammermill Copy Plus GOLDENROD®, or equivalent, to be used for field forms. It has proven to be the least annoying in direct sunlight for field recording data, maps, diagrams, and other descriptions.

Clear plastic sheets for printing outline overlays are 3M® or Labelon® Overhead Transparency Film. These films are specifically designed for different printers such as laser, inkjet, or plain paper.

These forms are printed here at 90 percent of their original size. To reproduce at full size on 8½- by 11-inch paper, set the copy machine for a 110-percent enlargement.

Page and figure numbers for examples of their use are given in the following list.

Table 5. Significant change table for nested frequency.

Using 100 nested frequency plot frames, the table below shows a significant change in frequency value at the 80% probability level. Enter the table at "Initial value" with the *previous* frequency value for the 5 transects (100 plot frames). Compare the *previous* value with the *current* value to determine if a significant change has occurred. A change is significant if the *current* value is smaller than the "Less than" value or greater than the "More than" value.

Less than	<u>Initial value</u>	More than	Less than	<u>Initial value</u>	More than	Less than	<u>Initial value</u>	More than

Figure 110—Construction details of a 1-m-tall meter board. The same measurements are used for the 1-m-tall folding board and for the 2-m folding board.

Meter Boards

Meter boards are used to mark photo points. They help in taking consistent repeat photographs if the camera is oriented on the “1M” of the board. Sharp exposure at the meter board is assured by focusing the camera on the “1M.” Meter boards also provide a size control in photographs that can be used to adjust the analysis grids when measuring the attributes shown in a photo. This section described how to construct meter boards.

One-Meter Board

Materials	Cost ¹
	<i>Dollars</i>
1 piece 1/2-in 4-ply exterior or marine plywood, finished on one side, 1 by 4 ft @ \$20/sheet	3
1 steel rod 3/16-in diameter, 36 inches long	1
Numerals:	
1 packet adhesive-backed numerals, 5-1/4 in tall, on a reflector, (need numbers 1, 2, 4, 6, 8)	4
(Alternative is 4-in nail-on numbers, 5 @ \$2/numeral)	(20)
1 4- to 5-in-long line or pocket level	4
1 16-oz can dull yellow spray paint, exterior	4
Screws:	
2 #4 5/8-in line level screws	
9 #6 3/4-in spike plate screws	1
A few feet of black electricians tape	1
Total	18

Meter boards are constructed from 1/2-in, 4-ply plywood, at least exterior quality and preferably marine quality (waterproof glue). Waterproof glue is desirable when sampling riparian areas because the meter board often will be placed in water. (Dimensions and layout are shown in fig. 110). Cut out according to the measurements shown in figure 110.

Prime the front of the board before painting. Then apply two coats of dull, textured, yellow paint to reduce reflection from the sun. Yellow is used for visibility. If dull yellow paint is not available, do not sand or smooth the front of the board. Unsanded roughness causes the paint to be rough, thus reducing glare. Most of the 12-oz pressure can will be required for two coats.

¹ Prices given are approximate as of 2000.

The numerals 2, 4, 6, and 8 should be black and at least 4 in tall. For good readability in projected slides, 5 in is even better. All illustrations in this publication show 5-in numbers. There are many sources for these, including paste-on numbers, numbers on a card that must be cut out, and nail-on numbers. I use 5-1/4-in-tall numbers on a reflective card with adhesive back. Each number must be cut out and applied to the painted surface. The "M" in "1M" is made from electricians tape, or it may be painted on.

Black marks at each decimeter and bands at top and bottom may be applied in one of two ways: paint them on at 2 cm wide or use black electricians tape, which is 3/4 in wide (1.8 cm). The top, bottom, and decimeter marks are used to adjust grid size before grid analysis of items in the photographs. Location of the marks on the meter board therefore must be positioned precisely (fig. 110).

A line level is attached to the back of the board at the top (fig. 111). This allows the board to be oriented vertically, which is essential for grid analysis, and it makes pictures look good.

Steel spikes are attached to the bottom of the board (fig. 112) to hold it in the ground. Steel rod, 3/16-in diameter, works well because it is strong enough to hold the board upright and small enough in diameter to be pushed into rocky soil. Spikes should extend 6 in below the bottom of the board (fig. 112). Rods come in 36-in lengths. About 30 in is required. Bend the rod into a "U" shape to match the dotted outline in figure 112.

For convenience, a carrying handle may be attached to the edge of the board near the 5-dm position.

Two-Meter Folding Board

Two-meter boards are used when shrubs or other vegetation exceeds the height of a 1-m board (fig. 113). They are, very simply, two single-meter boards attached by hinges and a barrel bolt so that either the 1-m or 2-m length may be used.

Figure 111—A line level is used to orient the board vertically. Obtain a 4- to 5-in-long line level and drill a hole in each end for a screw. Attach one end of the line level to the back of the meter board $\frac{1}{2}$ in (1 cm) from the top. Then orient the board vertically by using a carpenter's level along one side. Hold the board in position, adjust the line level to horizontal, and carefully screw in the other end.

Materials

Cost
(see footnote 1)

	<i>Dollars</i>
2 pieces 1/2-in 4-ply exterior or marine plywood, finished on one side, 1 by 4 ft @ \$20/sheet	6
1 steel rod 3/16-in diameter, 36 in long	1
Numeralals:	
2 packets adhesive-backed numeralals, 5¼ in tall, on a reflector, (need 2 each of 1, 2, 4, 6, 8)	8
1 4- to 5-in-long line or pocket level	4
2 16-oz cans dull yellow spray paint, exterior	8
2 strap hinges, 4-in size, heavy duty	5
1 barrel bolt, 5-in size, heavy duty	8
Screws:	
2 wood screws, #4 5/8-in line level screws	
9 #6 3/4-in spike plate screws	
1 #10 1/2-in sheet metal screw, for below the barrel bolt (sheet metal needed for hardness); 2¾-in washers	
10 #10 1-in hinge wood screws	2
8 #10 1/2-in barrel bolt wood screws	1
Several feet of black electricians tape	
Total	43

Figure 112—Spikes in the bottom of the board are pushed into the ground to hold the board upright. Use a 3/16-in diameter steel rod about 30 in long. Bend it into a U-shape as shown by the dotted line. It is placed under a plywood plate and held in place by nine screws. Leave about 6 in (1.5 dm) of rod below the board. Screws are positioned to hold the rod in place. (A) Insert a screw on each side of the rod at the bottom. (B) Insert three at the top to prevent upward and downward movement of the rod. (C) Place one at each side at top to prevent sideways movement. Drill out doweled to fit over the spikes for safety.

Figure 113—Use of a folding 2-m board to document height and growth of tall shrubs. This board is hinged in the middle and held upright by a barrel bolt. When folded together (fig. 109), it functions as a 1-m board. Here, the board has been unfolded to 2 m.

Figure 114—The 2-m board system. (A) Standard 1-m board with the top half folded underneath. (B) The folded board has been turned over to show the 2-m section.

Construct two 1-meter boards as discussed previously. On the first, construct with spikes at the bottom and numerals as shown. On the second, use “2M” at the top instead of “1M,” and add numeral “1” to each of the decimeter numbers as shown in figures 113 and 114. The numeral “1” can be made from electricians tape.

Figure 115 illustrates the hinge, barrel bolt, and position of the line level between the two halves of the meter board. Proceed as follows:

1. Refer to figure 115. Attach hinges (A) to plywood the same thickness as the barrel bolt and glued to both halves of the meter board. The 5-in bolt shown in figure 115 required 3/8-in plywood. These plywood blocks raise the meter board halves so that the barrel bolt will clear both its connecting strap (B) and the line level (D) when folded. Attach the hinge straps to the top board first. Then use a straight edge to align both halves in a straight line. Finally, attach the bottom straps to the bottom board while firmly holding both halves together.
2. Install the barrel bolt next. Position the barrel bolt at the very bottom of the upper meter board so the bolt drops down when the boards are erected. Place the barrel bolt strap (B) as close to the top of the bottom board as possible without the screws splitting the wood. The bolt should protrude about 3/8 in below the strap (figs. 115C and 116A). Insert a sheet metal screw and sufficient washers under the bolt end to hold it firmly against the strap to prevent flexing when the boards are unfolded (fig. 116B).
3. Position the line level on the bottom (1-meter) board where it can be seen from above when the boards are folded for 1-meter use, and from the back when unfolded for 2 meters (fig. 115D). The line level can be seen when the boards are folded by looking down through the strap holding the barrel bolt when it drops.

Figure 115—Hinges and a barrel bolt connect the halves of the 2-m board. (A) When installing hinges, attach to the top board first, and then align the boards in a straight line, and then attach the lower straps of the hinges. (B) The barrel bolt should be oriented to fall down when the board is unfolded. Position the bolt and its strap at the edges of the board halves so that the bolt protrudes about $\frac{3}{8}$ in below the strap. (C) Install an adjusting screw (fig. 116) to tighten the barrel bolt against its strap and stiffen the two boards when unfolded. (D) A line level is placed an inch half such that it can be viewed from above when folded and from behind when unfolded, as shown.

Figure 116—Adjusting screw and washer used to remove play between the barrel bolt and its strap, which will stiffen the two halves when unfolded. (A) Measure the distance between the bolt and the board. (B) Insert a round-headed sheet metal screw with enough washers to make the bolt fit firmly under the flange. Sheet metal screws are preferred because of their hardness. Pound the flange down if necessary.

Figure 117—Folding 1-m board specifications. (A) Cut a standard 1-m board at 4 dm and install hinges and a barrel bolt. This offset is used to protect the spikes (B). Assemble the board before painting and application of decimeter marks to assure correct measurements.

One-Meter Folding Board

If field transportation of a meter board is a concern, the 1-meter board can be made to fold. The hinge system is described and shown in figures 115 and 116. Figure 117 illustrates dividing the board at 4 dm to provide protection for the spikes.

Photograph Identification-Sheet Holder

Each photograph taken in photo monitoring should be identified. Plot photographs are identified by a form attached to a clipboard and placed within view of the plot form. General and topic photos taken of the meter board are identified by a form attached to a clipboard and positioned between the camera and meter board. Making the clipboard and a post to hold it are described.

Figure 118—Clipboard for displaying photo identification forms. A second clip (A) is taken from another clipboard and either screwed or riveted to this clipboard. Distance between the clipboard clips should be 10 ½ in to do two things: (1) hold the sheet in windy conditions and (2) not cover essential information. The clipboard is placed on the ground for plot photos or on top of a clipboard post (see fig. 119) to be set in front of the camera. When placed on the post, a screw (B) is inserted into the wooden block holding the ¼-in rod behind the clipboard (see figs. 119 and 121) to prevent the clipboard from rotating in the wind.

The clipboard is shown in figure 118. It is a standard 12-in clipboard with the addition of a second clip removed from another clipboard and attached by rivets or screws as shown. The critical factor is to place the clips no closer than 10 ½ in to avoid covering any information on the identification paper. Two clips are required to prevent the identification sheet from blowing in the wind.

Materials (see footnote 1)	Cost
	<i>Dollars</i>
2 clipboards 12 in long @ \$4.50/each;	
second clipboard for its clip	9
6 1/8-in diameter bolts or rivets to attach the second	
clipboard clip and straps for the clipboard post	1
2 1/4-in line guides or straps	<u>1</u>
Total	11

Remove the clip from the second clipboard and attach it to the first board with either two bolts or two rivets.

Figure 119—The clipboard post (A) in its compressed position ready to be inserted into the straps behind the clipboard. The 1/4-in rod slides into two 1/4-in straps on the clipboard. (B) These straps are positioned 4½ in apart and riveted (as shown) or bolted to the clip board with 1/8-in rivets or bolts.

Figure 119 shows the clipboard post in its compressed position. Two straps capable of having a 1/4-in diameter rod inserted are attached to the back of the clipboard in the middle, as shown. They are centered 6 in from each end and placed 4½ in apart so that the 5-in rod will engage each (fig. 119B).

The clipboard post is an adjusted pole, 1 in in diameter, with a spike on one end to push in the ground and a telescoping inside pole with a rod at the other end to which the clipboard is attached (fig. 119A). It is composed of telescoping plastic pipes each 18 in long (fig. 120A). It is 22 in long when compressed and 32 in long when extended (fig. 120B). An adjustable hose clamp is attached to the upper end of the larger pipe so that it may be compressed around the inside pipe to hold it in place (fig. 120).

Materials

Cost
(see footnote 1)

	<i>Dollars</i>
1-in CL 200 PVC pipe @ \$1/10 ft	1
3/4-in CL 200 PVC pipe @ \$1/10 ft	1
1-in diameter hose clamp	1
1/4-in diameter, 36-inch steel rod; piece, cut two 7-in pieces`	1
Several feet of black electricians tape	4
Total	8

Figure 120—Details for constructing the clipboard post. (A) The 1-in PVC pipe CL200 and 3/4-in PVC pipe CL200, which fits inside the 1-in pipe, are each 18 in long. When the 3/4-in pipe is inserted into the 1-in pipe and compressed, they are 22 in long. (B) The 18-in inside pipe has been extended 14 of its 18 in, for 32 in. The 3/4-in diameter spikes at the bottom and top both extend 5 in beyond the pipe and are imbedded into doweling inserted in the pipe.

Figure 121—Details of how the clipboard is placed over the rod as viewed from the edge of the clipboard. (A) The clip of the clipboard. (B) The edge of the clipboard, in this case an aluminum board. (C) The $\frac{1}{4}$ -in straps into which the $\frac{1}{4}$ -in rod of the post is inserted. (D) The $\frac{1}{4}$ -in rod of the post inserted into the clipboard straps. (E) A screw inserted into the wood doweling to hold the $\frac{1}{4}$ -in rod, which prevents the clipboard from rotating in the wind (see fig. 118). (F) A piece of doweling fitted inside the $\frac{3}{4}$ -in PVC pipe, which is drilled out for a $\frac{1}{4}$ -in steel rod and held in place by a screw. (G) A sawcut 2 in into the 1-in PVC pipe so that the pipe can be compressed by the hose clamp (H) to hold the inside pipe at the desired height. At H, the hose clamp is secured with electricians tape.

The clipboard post is composed of two parts (fig. 121). One is 1-in CL 200 PVC pipe and the other is $\frac{3}{4}$ -in CL 200 PVC pipe, both 18 in long. The $\frac{3}{4}$ -in pipe fits inside the 1-in pipe with some slack. If pipe specifications other than these are used, be sure that one pipe will fit inside the other. When compressed, the clipboard holder is 22 in tall. When extended with 4 in of pipe inside, it is 32 in tall (fig. 120B).

To make the clipboard post adjustable, saw down 2 in into the end of the 1-in pipe (fig. 121G). Attach a 1-in hose clamp an inch below the top of the pipe and secure it with electricians tape (fig. 121H). Tighten the hose clamp so that the inside $\frac{3}{4}$ -in pipe can just be moved up and down to adjust height of the clipboard above vegetation or other obstructions.

Figure 122—The 1-ft² sampling frame is made from 1/2-in PVC pipe. Inside measurement is 12 in square. The side opposite the handle is open to facilitate placement in shrubby vegetation. An 18-in-long handle facilitates placement of the frame.

**One-Square-Foot
Sampling Frame**

The 1-ft² sampling frame is used with stereo photographic sampling. It is constructed from 1/2-in-diameter PVC pipe and measures 12 in square (fig. 122). An 18-in-long handle reduces effort when placing the frame.

Materials	Cost
	(see footnote 1)
	Dollars
1/2-in-diameter PVC pipe, 10 ft long @ \$3/piece	3
2 90-degree, 1/2-in PVC elbows; 1 1/2-in PVC "T"	1
Total	4

Consider not cementing the elbows to the pipe so that the frame can be taken apart to transport. Figure 123 shows the frame disassembled with its carrying case. The case is made from canvas with a handle and two snaps at the open end.

Figure 123—A1-ft² sampling frame disassembled with its carrying case. The case is made from canvas with a handle and two snaps at the open end.

Figure 124—Nested frequency plot frame specifications. Measurements shown are inside dimensions. The four prongs must be cut 2 cm longer to provide for threading the ends and the aluminum back piece must be cut 2 cm longer to provide for 1/4-in tapped drill holes for the edge prongs.

Figure 125—Plot locations in the nested frequency plot frame. The smallest is rated “4,” next largest a “3,” half the plot frame is rated “2,” and the rest a “1.” Plants rooted in each section are given the assigned rating, which is recorded by species.

Nested Frequency Sampling Frame

Nested frequency is a sampling system designed for low variability rates among observers; it is based on statistical analysis to detect change. A plot frame, 1/2-m square, with four sizes of nested plots is used (fig. 124). Species are recorded and given a value when rooted within any of the four subplots.

Values are assigned based on plot size (fig. 125). Species numerous enough to fall within the smallest subplot are rated highest to reflect their greater density. Species are recorded starting with the smallest subplot (4) and proceeding to larger subplots. Once a species is recorded, do not repeat its presence in a larger subplot.

Figure 124 specifies plot dimensions. Please note length requirements in the materials list below. The steel rods must be cut 2 cm longer so they can be threaded and screwed into the aluminum back piece. The aluminum back piece must be 2 cm longer than the dimensions shown in figure 124 to accommodate tapped holes for the outside rods.

Materials

Cost
(see footnote 1)

	<i>Dollars</i>
1 tap and die set for 1/4-in steel rod	(borrowed)
3 1/4-in steel rods, 36 in long:	
3 pieces cut 52 cm long, threaded for 2 cm (effective length 50 cm)	
1 piece cut 7 cm long, threaded for 2 cm (effective length 5 cm)	3
1-in by 1/4-in aluminum bar stock cut 52 cm long @ \$10/6 ft (drill and tap 4 holes, each 1/4-in diameter, at 1, 6, 26, 51 cm)	4
5 wing nuts for 1/4-in threaded steel rod	1
PVC pipe 1/2-in diameter SCH40 cut 50 cm long, @ \$3/10 ft	1
Total	9

Figure 126—Method for attaching the nested frequency prongs to the 1-in by 1/4-in aluminum back piece. (A) A 50-cm prong is shown threaded and ready to screw into the aluminum back piece. Next to it is the 5-cm-long prong attached. The 5-cm subplot is identified by the black mark on the 50-cm prong and the end of the 5-cm prong. (B) The center 50-cm prong is shown screwed into the aluminum back piece and through the 50-cm handle, with a wing nut ready to tighten the handle to the back piece.

Sharpen the ends of the four prongs to a 45-degree angle. These points are where ground cover items are recorded, such as bare ground, gravel, or rock.

Screw the threaded rods into the aluminum back piece (fig. 126A). Secure the rods with wing nuts. Be sure the measurements shown in figure 124 are met.

The 50-cm PVC handle is cut out and attached (fig. 126B). Cut one-third of the way through the pipe 1 in above its end to fit over the aluminum back piece. Then, from the bottom and starting in the center, cut at an angle to the upper cut. Finally, drill a 1/4-in hole to match the hole at 26 cm in the aluminum back piece (fig. 126B). Assemble as shown in figure 126B.

Figure 127—The disassembled nested frequency plot frame is shown with its carrying case. Notes on the aluminum back piece show percentage of the plot frame occupied by the 25- by 25-cm subplot (25 percent), 25- by 50-cm subplot (50 percent), and the 5- by 5-cm subplot (1 percent).

Paint the frame with dull yellow paint. When dry, paint the black marks at 5 and 25 cm on one prong and at 25 cm on the other prongs. These marks identify the various subplots sizes shown in figures 124 and 125.

The plot frame may be disassembled for carrying as shown in figure 127.

One-Square-Meter Sampling Frame

One-square-meter photo plot frames are designed to replace Parker's (1954) three-step method using a 3-ft by 3-ft plot frame. Both are used in photographs taken at an oblique angle. His plot frames were made from two 6-ft folding rulers, the joints of which could be used to draw a grid on a photograph. This 1-m² frame is marked off in 2-dm increments (fig. 128).

Materials

Cost
(see footnote 1)

	<i>Dollars</i>
3/4-in SCH40 PVC pipe @ \$2/10 ft, 2 required	4
90-degree 3/4-in PVC corners SCH40, 4 required	2
4 by 8 inch, 1/2-inch thick scrap plywood	(scrap)
2 screws #6, 1 in long	
Several feet of black electricians tape	4
Total	10

Cut the 3/4-in PVC pipe into four 1-m lengths (fig. 128A). Be precise because the pipes, when inserted into the elbows, fit at exactly the elbow corner. Do not glue the pipes to the elbows. The frame will be adequately stable with the pipes simply pushed into the elbows and then can be broken down for transport (fig. 128B).

Figure 128—The 1-m² plot frame (A) is marked off in 2-dm increments. Inside measurements are 1-m per side. The ¾-in pipe may be measured precisely and inserted into the elbows because the elbows have a stop at the exact position of the elbow bend. Do not cement the elbows to the pipe because the plot frame can be disassembled for easy transport in its canvas carrying case (B).

Next, measure out 2 dm on all four pipes and circle the pipe at these locations with electricians tape to mark a 2-dm grid system (fig. 128).

In figure 128, a 1/2-in-thick piece of plywood measuring 4 by 8 in (1 by 2 dm) has been attached to identify the meter plot frame. The “1” and “M” are made with 3/4-in-wide electricians tape. The plywood is attached with two screws through the board and into the PVC pipe. I use the identification for slide talks to quickly identify the size of plot frame.

Figure 129—A method is shown for estimating small increments of cover. In a 1-m² plot frame, 1 dm² is 1 percent cover. This represents about the front one-third of my foot. Because a 1-m² plot is 3.4 feet on a side, each large step represents 1 percent cover so long as the cover is represented by each and every step. An area 2 by 2 dm is 4 percent cover, about 1.3 of my foot. I now have a measuring system for estimating cover of items I encounter while walking across an area.

Figure 129 reflects a system I have found useful in estimating cover of vegetation or soil surface items. An area 1 dm by 1 dm is 1 percent of a square-meter plot. A square-meter plot, being 3.4 ft on a side, is a little longer than the stride of a person about 6 ft tall. The front one-third of my foot is about 1 by 1 dm (fig. 129). Therefore, each time I take a long step, any vegetation that covers the front one-third of my foot is 1 percent of the cover. But the vegetation must approximate that area for *each and every step*. If it does not, then canopy cover of that item is less than 1 percent.

Each 2-dm area is 4-percent cover, a little more than one of my whole feet. Thus, when walking through an area, I have some reasonably firm idea of how to estimate cover of various items.

Robel Pole Sampling System

The Robel pole (Robel and others 1970) offers a way to document stubble height of herbaceous vegetation. They tested various systems for observing stubble height and settled on a pole marked in 1-in increments and set 4 m from an observation position 1 m high. Figure 130 shows specifications for making the Robel pole system.

Figure 130—Robel pole specifications and criteria are shown. (A) A 2.0-in diameter PVC pipe is used for the Robel pole and 1½-in pipe for the camera height pole. These diameters permit the camera height pole to be inserted into the Robel pole (B) for carrying. A tent stake for supporting the Robel pole is carried in a person's pocket. In A, the Robel pole is 1.2 m tall with an eye at 1.0 m. The camera height pole is 1 m tall to which is fastened a 4-m measuring line. When working alone, use a tent stake with 2 m of line to hold the Robel pole vertically while pulling the 4-m line taut.

Materials

Cost
(see footnote 1)

	Dollars
2-in diameter CL200 PVC pipe @ \$3/10 ft (cut 1 piece 1.2 m for the Robel pole)	3
1.5-in diameter CL200 PVC pipe @ \$3/10 ft (cut 1 piece 1.0 m for the camera-height pole)	3
20 ft 1/8-in diameter nonstretch rope	1
1½-ft 1/4-in diameter steel rod (cut 2 pieces 8 in long)	1
2 #6 size eye screws; 1 6-in tent stake	2
1 snap with ring; several feet of black electricians tape	3
Total	13

The Robel pole system consists of two poles and a 4-m section of line attached between the poles. Figure 130 lists the specifications permitting the camera-height pole to be placed inside the Robel pole for carrying. Figure 131 illustrates construction and marking of the Robel pole and details.

Figure 131—(A) The Robel pole is marked at 1-in increments with black electricians tape. Alternate inch increments are inscribed with permanent black markers for every odd-numbered inch. Steel rods $\frac{1}{4}$ -in diameter extend 6 in below the Robel pole and the line pole. The Robel pole rod is protected by doweling drilled out for $\frac{1}{4}$ -in steel rod. Steel rods are secured inside the PVC pipe by doweling. (B) An eye is attached to the Robel pole 1 m aboveground. After screwing in the eye, remove it and cut off the sharp end, then replace the eye. Cutting off the sharp end provides room for the camera height pole to be inserted into the Robel pole (fig. 130B). A 4-m line, secured by a nail, is wrapped around the camera height pole. It is snapped to the eye on the Robel pole to measure consistent distance between Robel pole and the camera. The camera height pole, 1 m tall, provides a consistent camera height when the camera is positioned at the top of the pole.

Figure 132—A leveling board for taking overhead photos of tree canopy cover measures $4\frac{1}{2}$ in by 6 in and has a two-way level attached. It is made from scrap $\frac{1}{2}$ -in plywood.

Figure 133—The camera leveling board is used to consistently rephotograph the tree canopy. Place the leveling board on top of the meter board for consistent height above the ground. Place the meter board at a right angle to the transect line. Move the meter board sideways to center the cross-transect bubble, then tilt the level board to center the down-transect bubble, and photograph.

Camera Leveling System

Photographs taken looking up at the tree canopy require a camera leveling system for consistent rephotography. The system described here uses the meter board top as one axis for consistently orienting the camera and a leveling board for the other axis (figs. 132 and 133).

Materials	Cost (see footnote 1)
	<i>Dollars</i>
1 2-way level or 2 line levels	4
4½- by 6-in, 1/2-in thick, scrap plywood	(scrap)
Total	4

Figure 132 illustrates the camera leveling board's dimensions and placement of the two-way level. Figure 133 illustrates uses of the leveling board. Place it on the top edge of the meter board, move the meter board left or right to center on the cross-transect level, then tilt the board to center the down-transect level. Move your head out of the way and photograph.

Figure 134—Double camera bracket for use when photographing in both color and black and white. The bracket is made from 1- by 1/8-in stock aluminum bar with holes drilled to mount the cameras. Identical cameras are recommended to simplify camera adjustment. Figures 135 and 136 illustrate construction details.

Double-Camera Bracket

Two cameras usually are needed to photograph in both color and black and white. A bracket holding both cameras together provides for simple and effective manipulation of the cameras (fig. 134). Identical cameras simplify adjustment. When ready to photograph, simply shoot with the top camera, then the bottom, and advance the films.

Materials

Cost (see footnote 1)

	Dollars
1 6-ft piece aluminum bar stock, 1 in wide by 1/8 in thick (cut a piece 18 in long)	8
Instant thumb screws:	
2 1/4-in diameter standard 20 thread, 3/8-in shank screws	1
2 instant thumb screws	1
Total	10

Figure 135—The double-camera bracket (A) with thumb screws to attach the cameras. Washers may be needed if thumb screw shanks are too long. (B) Thumb screws come in two parts: the shank and the head. The head must be forced onto the shank by using a vise (C).

The aluminum bar stock, cut to 18 in, is bent into equal 6-in segments to form a “U” (fig. 135A). Then, 1/4-in holes are drilled 2 1/2 in from the ends (fig. 135A) to hold the cameras. Be sure the holes will place the cameras where the rewind buttons will be accessible (fig. 136B). Next, on the aluminum bar make two 1/4-in cuts, 1/2 in apart, into the aluminum toward the front of the camera and bend the 1/2-in piece upward to about a 30-degree angle (fig. 136A). Do not bend more than 30 degrees or the aluminum will break. These tabs will prevent the cameras from rotating on the bracket.

Assemble the thumb screws, which come in two parts — the shank and the thumb head (fig. 135B). Be sure the shank will fit the camera mounting socket. A 1/4-in diameter, 20-thread shank 3/8 in long will work. Press the head onto the shank as shown in figure 135C using a vise. Heavy pliers usually do not apply sufficient force to seat the thumb head.

Figure 136—Two factors are important in attaching the camera to the bracket. (A) Make two ¼-in cuts into the front of the bracket, ½ in apart, and bend upward no more than 30 degrees to prevent rotation movement of the camera. (Bending them farther may break them off.) (B) Be sure the bracket clears the rewind button so that film may be changed while the camera is attached to the bracket.

Fenceposts

Flimsy fenceposts are available at builders supply outlets such as Home Depot®. They are listed as “light duty” stamped metal fenceposts. Measured across the top, the long axis is 1¼ in. Medium duty stamped fenceposts measure 2 in. Light duty posts may have to be ordered.

Identification Tags

Orange colored, aluminum tags suitable for installing on witness sites to identify a monitoring location may be obtained from:

Dixie Steel and Sign Co.
P.O. Box 54616
Atlanta, GA 30308
Phone: 404-875-8883
Fax: 404-872-5423

Obtain a tool-steel inscriber to inscribe directions and distances to camera locations and photo points directly on the tags. The tags are about 12 gauge thickness with black and orange paint.

Appendix D: Photo Monitoring Filing System

Contents	297	Introduction

	301	Map1
	301	Photo-Mounting Forms
	301	Summary Forms
	301	Envelopes for Negatives
	302	Slide Files

Introduction

The concept of photo monitoring implies repeat photography, which in turn suggests the need for a filing system where, over the years, one can regularly deposit their photographs and data. This appendix describes some attributes of filing systems I've found useful over the last 40 years.

Figure 137—File folder contents for the Crooked River National Grassland trend cluster C3. I use several sizes of expanding folders: 2-fold shown here, 4-fold, and 8-fold to fit the file size. Each folder is labeled and the last date of sampling is attached to the upper right corner (arrow). All items pertaining to the sample location are included in the file: (A) general area map (fig. 72), (B) the form "Sampling Site Description and Location" for a plot layout map (fig. 82), (C) a form for attaching photographs and recording data shown here as the "Photo Trend Sample - Nested Frequency" (figs. 83-85), (D) data summary forms shown here as "Nested Frequency Transect Data" (figs. 86 and 87) and "Nested Frequency Cluster Summary" (figs. 88 and 89), (E) trend interpretation using "Range Trend Rereadings" (figs. 90 and 91), and (F) clear plastic holders for slides (fig. 139). Not shown are black-and-white negatives in their envelopes identified by date, cluster, and transect.

Office Filing System

Office organization of the filing system presumes that each monitoring location is completely contained in its own folder (fig. 137). Consider three alternatives for filing these folders: by (1) date of rephotography, (2) topic of the study, or (3) geographic location of the study.

Date of Photography

Date of photography may be season of year, such as Pole Camp in spring, summer, and fall (fig. 20); once each year at a specific date, such as herbage production (fig. 22); irregularly based on disturbance such as logging (figs. 29, 50, and 51); or at specified intervals, such as every 5 years—the three intervals between 1977 in figure 46 and 1991 in figure 48.

An advantage of organizing by date is having files immediately available each year according to their schedule. This means that topics of sampling and geographic locations are interspersed requiring search of all files. I place the date information on the upper right corner of the file rather than file by date.

Topic Being Monitored

The topic being monitored determines the purpose for monitoring and the kind of vegetation under consideration. Topics may be exclosures (fig. 137), livestock trend sampling (figs. 75, 83, and 92), sagebrush-grass (figs. 75, 83, and 92), logging effects (figs. 21, 50, and 51), herbage production (fig. 22), or livestock utilization (figs. 20 and 106-108).

Similar topics are filed together, such as logging with overstory removal (fig. 21) and a single light thinning (figs. 50 and 51) in ponderosa pine. All logging may be put together or all ponderosa pine may be located together. If logging is the topic, salvage of beetle-killed lodgepole pine (figs. 46-48) would be filed with it. Decisions must be made on organizing the files by topic, none of which will prove wholly satisfactory.

Geographic Location of the Study

Geographic location is determined by the closest available motel, access by major road, or distance to travel. My work from Portland, Oregon, covering two states, is organized by towns that gave good access and an acceptable motel. When going to an area on other work, I look in its geographic file to determine if any photo monitoring locations are due for sampling. What might be combined between current work activity and photo monitoring? Are there any monitoring sites in the neighborhood of the work area or on the route? Dates on the files are the first consideration. Is the work activity occurring about the same date as required for sampling? Consider organizing files by date and then by topic within a geographic file. Another approach is to allot several days for monitoring. Having files by location greatly facilitates travel planning and might save considerable time in visiting each site. Filing by location has been my choice for many years.

Figure 138—Three pages of filing system form “Camera Location and Photo Points” overlapped to compare changes between three dates. These are figures 46, 47, and 48 located by the map in figure 45. Essential information for making comparisons is in the upper right portion of the form: date and camera location. Overlay the forms so that photographs can be compared as shown. Camera orientation in close landscape photography can be a problem resulting from no meter board or permanent item on which to orient the camera. Compare photo B for 1977 and 1978 with B for 1991. The horizon is similar for the first two but quite different for 1991, a situation to be avoided. Also notice the variation in the road crest in the A photos.

File Contents

All information pertaining to a photo monitoring project should be placed in a single file. This may entail duplicate copies of some items, such as a request and authorization for a study, which might require filing in an office administration folder as well as in the project folder. Long-term investigation, like photo monitoring, is significantly enhanced when historical documents are included in the file.

Consider six kinds of items to include: (1) authorization, approval, or justification for the project; (2) maps to find the monitoring location—a general map noting the location and a site-specific map diagramming the sampling layout; (3) photo-mounting forms that also may be used to record data, such as transect sampling systems; (4) envelopes for negatives, either color or black-and-white, or both, digital memory cards, or compact discs (CDs); (5) summary forms when data are collected; and (6) plastic sheets for holding slides.

Authorization, Approval, or Justification

Document initiation of the photo monitoring project. This may entail copying instructions or policy from an organization, a written request to monitor and subsequent approval, or those parts of an environmental impact statement requiring monitoring of specific activities. If an environmental impact statement, or similar document, is required, include it. Assume that someone totally unfamiliar with your organization's policy, protocol, or operational procedures may pick up the file and will have everything they need to understand and use the monitoring system. This has proven invaluable in monitoring projects older than 20 years because policy, protocol, and operational procedures change.

Maps

Two maps always should be included in the monitoring file (fig. 137): a general map showing how to find the monitoring site (fig. 72), and a detailed site map of the monitoring system (fig. 73). These maps should be in such detail that a person new to the area can find the monitoring location and do the rephotography.

Photo-Mounting Forms

Effective use of photographs in monitoring suggests that they should be mounted to facilitate comparison. The filing system forms in appendix B are organized so that photos are mounted on the right, underneath the date and camera location. Pages may be overlapped to compare any number of photos by date (fig. 138).

Two kinds of photo-mounting forms are provided: those for topic or landscape photography where measurements are not made (figs. 44, 45, 46-48, and 138), and those for transect sampling where measurements are recorded in the field (figs. 67-69, 75-77, 83-85, 93-95, 99-100, and 106-108). The form shown in figure 137 is a transect form (figs. 83-85). These forms have space for 3- by 5-inch photos.

Summary Forms

Summary forms are used with transect sampling to summarize and interpret the data. One important form is "Range Trend Rereadings," used to compare data among years (figs. 79-80 and 90-91). It may be used with several of the sampling systems. Other forms are designed for a specific system, such as nested frequency (figs. 86-89; tables 2 and 3) or Robel pole utilization (fig. 109).

A different kind of summary form is used with grid analysis. It is a piece of clear plastic (fig. 54) labeled with sampling date, site name, and item, on which outlines of items (shrubs in this illustration) are drawn (figs. 55-56, 60, and 68-69). The outlined sheet is placed on a grid (figs. 58 and 70), which is adjusted in size to the outline, and the number of intersects within each outline are recorded on a summary form (figs. 59 and 71). The photograph, sized grid, outline sheet, and summary form are all filed.

**Envelopes for
Negatives**

Negatives, color or black-and-white, should be kept in the monitoring file. I find that keeping them in the envelopes from processing is quite satisfactory; there is a compartment for the negatives and one for the pictures. I routinely have two prints made: one for mounting and another as a spare. The envelope is labeled with date of photography, monitoring location, and camera-photo point identification.

Each picture on the negative should be identified by a photo identification sheet placed within the camera's view. After several sessions of rephotography, identifying which negative was taken in what year can be impossible. This becomes a serious threat to integrity of the project when prints are made simultaneously from several years of rephotography of the same photo point. How might the various negatives be returned to their proper envelope?

Digital images may be stored in the file by any of three methods: (1) memory cards with their containers, (2) transferred to a CD, or (3) stored on the hard drive of a computer with essential identifying information. Directions to find the computer filing system should be placed in the file.

Figure 139—Slides filed in clear plastic sheets facilitate comparison among years. I use either of two systems: four columns by date using the slide holder in portrait view (shown here) or five columns by date using the slide holder in landscape view where five sets of slides are compared. Shown here are slides of figures 46 through 48 and 138. This system of four dated columns also was used in figure 137, where four sheets were required to hold slides for each date.

Slide Files

Slides may be filed in two kinds of holders: rigid opaque plastic or flexible clear plastic sheets. Rigid holders protect the slides on only one side, the other is open. Clear plastic have pockets (2 by 2 in) into which slides are placed (fig. 139). They are protected on both sides. A product **not** having PVC in its makeup will not damage the slide itself (for example, ClearView™). Some flexible pocket sheets will adhere to the slide and damage the emulsion. Slides do not fall out of rigid holders but they do tend to fall out of flexible pocket holders. Even so, my preference is for flexible pocket holders because they take only one-third the filing space of rigid ones.

Slides may be returned to you from processing in either paper or plastic mounts. Paper is less rigid and easier to write on but will hang up in projectors more often and is useless if ever dampened. Plastic requires felt-tip pens for effective writing such as Sanfords Sharpie® Ultra Fine Point Marker, the same one used for drawing outlines on clear plastic sheets. I specify “plastic mounts,” “number only,” and “do NOT date” when I have slide film processed.

All my slides are dated by when they were taken, not when processed. I use a “000” size date stamp with year, month, and day. A stamp significantly reduces time handling the slides. Each should be identified by a “photo identification” form within the view (figs. 26, 33, 67-68, 75, 83, 93, and 106). In addition, I label each slide for easy recognition and add any pertinent information (fig. 139).

Consider filing slides in columns by date (figs. 137 and 139). If there are five slides for a photo point, I file them in landscape orientation (horizontal) in the slide holder. This permits comparing five sets of slides from five different dates on one sheet. If there are four or less slides, I use columns in portrait (vertical) orientation (fig. 139) where four columns may be compared. Using a light table, one can view a number of photo points over considerable time. In figure 139, only photos A and B are shown covering a time span from 1977 to 1997.

Appendix E: Photo Techniques

Contents	303	Introduction
	305	Composition of Photographs
	313	Light
	323	Relocation of Photographs

Introduction

This appendix is devoted to several topics with much of the discussion occurring in the figure captions.

Hedgecoe (1994) introduces his treatise on landscape photography by discussing learning how to see. What the eye transmits to the brain is not what the camera records. The eye scans a topic for several seconds while the brain filters out the surroundings. Our eyes perceive fine detail over just a small area in the middle of the view. The camera records a fixed rectangular part of the scene with no overt identification of a topic. The view recorded has constrained edges, unlike the movement of eyes. A photograph, therefore, must be purposely oriented to record what the eye and brain see.

Johnson (1991) suggests asking several questions to help resolve eye and camera relations: Why am I taking this picture? What is the purpose of this picture? What will the picture demonstrate? What appeals to me in this scene? and What am I looking for? "Looking for," the topic of interest, might occur in one of three planes: foreground, middle distance, and far distance. These are relative distances between the camera and the horizon. Close photography might have only 200 yards from the camera to the horizon or back of the scene (fig. 26), in contrast to 10 miles in a general landscape view (fig. 16). Composing the picture to focus on the topic is an important objective.

Figure 140—Comparison of (A) landscape and (B) portrait camera orientation. Hedgecoe (1994) considers landscape camera orientation as peaceful and stable and portrait orientation as active and unstable. Do you agree?

Composition of Photographs

Hedgecoe (1994) suggests that camera orientation helps to convey a message. Landscape (horizontal) orientation suggests peaceful and stable conditions, and portrait (vertical) orientation connotes active and unstable situations. Figure 140 compares these orientations.

Mobility of camera location is more valuable than a battery of lenses for photographic composition (Hedgecoe 1994). By moving around to view the topic, one can totally change the composition of the picture. Different foreground and background elements may be aligned, or detail close to the camera may be avoided or included. The point is to make the picture emphasize the chosen topic.

The next consideration is composition: First identify the topic of interest, and then position the camera to enhance the topic. Hedgecoe clearly discusses the “rule of thirds,” which is based on the golden mean, a 1:1.62 ratio, about the dimensions of a 35-mm image, which seems to be the ratio most pleasing to people from western cultures (fig. 141). It suggests that about 33 percent is a valuable percentage to use for positioning the topic. In landscape photography, it is used to position the horizon: one-third sky to two-thirds land, or as shown in figure 135, one-third land and two-thirds sky. The next “third” is to frame the picture on at least one side with something. And the last “third” is to divide the land (or sky) into thirds by use of an angle. The angle may be a road, change in vegetation, crest of a hill, cloud formation (fig. 140), or other item. Perhaps the mnemonic “one-SAT” will help recall “one side, one angle, one-third.”

Figure 142 begins a series illustrating this adage. Figure 143 is a broad view of the landscape used for illustration. Figure 144 is a common type of camera orientation, placing the horizon in the center of the picture. Lowering the camera, as in figure 145, illustrates a one-third horizon; in figure 146, the camera moves to the right to frame the scene. One angle is represented by the slope. Figure 147 is the actual scene taken near the Snake River in Oregon, showing the topic of terracing on the near slope resulting from livestock grazing and no terracing on gentler slopes.

Figure 148 illustrates the “thirds” concept but reverses one-third sky for one-third land to emphasize the topic of spring rain showers in the Great Basin. (In reality, only one-fourth is land.) In photo (B) the camera was repositioned to frame the picture with sagebrush and to include a fence for the “angle” and as a perspective on scale.

Pattern is use of contrasting objects such as a house in a field, row of trees, hills and a valley, or dramatic differences in vegetation as shown in figure 149. The topic was a meadow and its adjacent forest. Pattern also is illustrated in figure 150 but in a dramatically different way. Here pattern is related to texture of the siding compared to the roof and ground.

Text continues on page 313.

Figure 141—The “rule of thirds” depicted with a 35-mm image. Divide the image into thirds and use the intersection of the lines as a guide for topic location. In portrait photography, a person’s face or other item of interest is located at one of the circles. Landscape photography uses a modification as shown in figure 142.

Figure 142—Figures 143 through 147 illustrate the concept of “thirds” (Hedgecoe 1994) or the concept of “one-third, one side, one angle” for placing the topic of interest in a photograph. “One-third” suggests that only one-third of the picture should be sky or land. In figure 142, only one-third is sky. “One side” suggests framing the picture in some way, here with a tree. “One angle” calls for some line in the picture at an angle. This diagram is expanded to a real landscape diagram in figure 143.

Figure 143—A basic scene. Orientation of the camera will be further illustrated in figures 144 through 146.

Figure 144—Here the camera focus has been placed on the horizon resulting in half sky and half land. Compare to figure 147A.

Figure 145—The camera has been lowered to one-third sky providing some focus on the foreground topic of a rippled slope. Compare to figure 147B.

Figure 146—The camera was moved sideways to the right so that a tree would frame the picture. Here, four landscape photography concepts are illustrated: (1) one-third sky; (2) one-side framing; (3) one angle, the crest of the foreground slope; and (4) topic of the foreground rippled slope. The rippling (terracing) was caused by livestock use. These views are shown in figure 147.

Figure 147—**A**, **B**, and **C** correspond to figures 144, 145, and 146, respectively. Exposure is an important consideration in landscape photography. In **A**, the land has been underexposed because the camera light meter was overly influenced by the bright sky. Expose for the topic of interest. If serious photography is contemplated, always take at least three exposures: one at what the meter says, one an f-stop less, and one an f-stop more.

Figure 148—Reversing the “one-third sky” rule is necessary when the topic is weather. (A) Land was reduced to about 25 percent to emphasize spring rain clouds over the Great Basin. (B) Moving the camera a few feet uphill provided framing with sagebrush and a fence line, which provides scale and an angle. Also see figure 140.

Figure 149—The topic here is a meadow. (A) The horizon halves the picture. (B) The camera was turned 20 degrees to the left and orientation lowered for one-third sky to show an extension of the meadow into the distance. This provided a break in the meadow edge and functions as an “angle.” (C) The scene was framed by a tree. This figure also illustrates pattern by the forested hill and smooth pasture.

Figure 150—A totally different application to define the topic with one-third, one side, and one angle is shown with a structure. (A) A perfectly nice documentary of a country organizational building with one-third ground. (B) Adds a converging angle while preserving the name. (C) Simply frames the picture.

Figure 151—A framed landscape view is shown with the topic of a farmstead. Buildings are used to provide scale as is the fence. Backlight (sun shining towards the camera) creates a halo effect around each tree below the farm to give a three-dimensional effect.

Perspective or scale is provided by objects of known size; for example, the farm buildings in figure 151. In figure 148B, the fence line provided both an angle and a sense of perspective. Figure 149 could have been enhanced by an object in the meadow to indicate how wide it is.

Change in camera focal length is another method for dealing with composition and emphasizing a topic. Figure 152 compares two focal lengths and their effect on emphasis of ponderosa pine savanna. Figure 153 illustrates change in topic with change in focal length. The topic changes from an island in a river to a sweeping bend in the river with an island.

Composition may be summarized as follows: define a topic (What do I want to show?), apply the one-SAT concept (one side, one angle, one-third), use pattern to emphasize the topic, and provide perspective for the topic.

Light

Light is abused more often than used. It may be used to highlight objects, put a three-dimensional effect into a landscape, create unsolvable problems with shadows, and wreak havoc with a topic when sky and ground exposure are being reconciled. Abuse of light results from inattention to exposure and lack of time to photograph in suitable lighting conditions.

Sun may be used to enhance a three-dimensional effect in a two-dimensional photograph (figs. 151 and 154). Sun from behind the topic, particularly vegetation, tends to shine on the outside leaves while making a shadow in back. This forms a “halo” effect setting off individual plants and simulating a three-dimensional effect. Figure 155 illustrates the effect in grass, shrubs, and trees. Notice how the trees stand out as individuals in figure 151. The halo effect is summarized in the proverb of “photograph before 10 and after 3” when the Sun is low enough to create a good halo.

Text continues on page 319.

Figure 152—Effect of focal length is important in photograph composition and topic identification: (A) 50-mm lens on a 35-mm camera 10 m from the meter board emphasizing savanna ponderosa pine, and (B) 35-mm lens on the 35-mm camera from the same camera location but the meter board has been moved to 7 m making it the same size as in A. Scale of the grassland has been increased. Which picture more honestly illustrates forest savanna?

Figure 153— A second use of focal length is to change perspective in a photograph. The setting is an island in the Columbia River. Focal lengths were (A) 70-mm, (B) 50-mm, and (C) 35-mm on a 35-mm camera. In A, the island is the topic; in B, the island and river are both topics (which creates a dull photo); and in C, a sweeping curve of the river is the topic with the setting of an island.

Figure 154—Light position affects emphasis on vegetation. **(A)** Photo taken into the Sun so that the subject is backlit, which produces a “halo” around the edges and a shadow away from the Sun. The halo highlights vegetation and tends to give the picture a three-dimensional effect. An old adage says to photograph “before 10 and after 3” so that the Sun is low enough to enhance the halo effect. **(B)** The Sun is shining on the front of the vegetation (frontlight). Notice in B how the hills in the distance stand apart from each other owing to haze in the air.

Figure 155—A second example of how backlight (**A**) versus frontlight (**B**) affects the highlighting of vegetation. The halo effect is well illustrated by the trees in A.

Figure 156—Overcast or full sunlight has major effects in shadow formation, a particularly serious consideration in forests. Overcast days (**B**) produce no shadows. Compare to full sunlight in **A**. With black-and-white film, the shadows may be “dodged” during the enlargement process to bring out much detail. Color film unfortunately has only about half the latitude of black-and-white film for shadows, so particular care must be taken when adjusting exposure. Slides cannot be dodged.

Sunlight compared to overcast skies has advantages and disadvantages. Overcast provides no three-dimensional effect and sunlight produces shadows. Figures 156 and 157 illustrate the disadvantages of shadows.

Camera exposure setting is a key to good use of light. Figure 147, A and B, illustrates the effects. In figure 147A, the exposure was overly influenced by the bright sky, which resulted in underexposure of the land. Determine the camera exposure for the brightest item close to the topic (sky or vegetation in full sunlight) and then for the topic or darkest item at the topic. Average the exposures. If you have any doubt, take three shots: one at the average, one an f-stop under, and one an f-stop over the average. Figures 156 and 157, however, illustrate a problem. The shadow is too dark and the sunlight on the vegetation too bright to be properly exposed, even with black-and-white film. Black-and-white film has about twice the latitude of color; color latitude is about one f-stop above and below average, and black-and-white film is about two f-stops.

Camera exposures in landscape photographs, particularly those showing areas more than 2 mi in the distance, should be set at a minimum of three f-stop settings: the light meter reading and one f-stop below and one above. When distance exceeds 2 mi, haze in the air influences the light meter to indicate less brightness than the land actually is reflecting, which causes overexposure of the land. In these cases, consider taking photos at both one and two f-stops additional exposure. Aerial photography suffers the same problem.

The effect of shadows and poor exposure in photographs may be partially corrected on prints (not slides) by dodging during enlarging. Dodging entails use of a cotton swab $\frac{1}{2}$ to 2 in in diameter or a piece of light cardboard with a hole in it $\frac{1}{2}$ to 2 in in diameter. Both should be very ragged around the edge to avoid creating a harsh edge in the finished print. During enlargement exposure, wave the swab above the overexposed area to cast a shadow and reduce the exposure time for that area. For underexposed areas, use the cardboard with the hole to shade most of the print and allow longer exposure to bring out details. Digital images may be enhanced by computer.

Figure 157—This example is taken at the same photo point as figure 156: (A) overcast and (B) a clear day with full sunlight.

Figure 158—Relocation of photographs may be difficult when disturbance has occurred. In 1963, the centerline was established with a rock at 1 and the side of a large tree at 2. The arrows, A and B, indicate large rocks present in all photographs but not on the centerline; they help to locate the site and to validate the location. Left-side triangulation is identified by arrows at 3 showing the distance between a large tree and a small one. Right-side triangulation at 4 is identified by the side of a large foreground tree and one in the background. These triangulate the camera location. In 1974, the same items are shown without a meter board. Selection cutting occurred after 1974 with results shown in figure 159.

Figure 159—By 1987, selection cutting had removed the right foreground tree and the tree in the background located at 4 in figure 158, which eliminated the triangulation point. The rock at 1 was missing but the large tree in the background at 2 was present. Left-photo triangulation was still identified at 3. By 1996 after final overstory removal, all original vegetation orientation references were missing. Finding the location is facilitated by rocks at A and B, particularly B with its permanent location at the base of a tree. Precise relocation of both camera and photo points (meter board) were possible only from permanent steel stakes in the ground. Note soil hole spoils in the foreground. There has been no colonization of B or C horizon by native species in 33 years.

Relocation of Photographs

Figure 158 illustrates relocation of a camera location and photo point. The procedure is similar to that shown in figure 38. On the original photo (1963), draw a central line. A rock in the foreground and a tree in the background help establish the line. Remember, the meter board will not be in position when the site is next visited, so it cannot be used for the center line. Then establish reference points at the edges of the photograph to triangulate the camera location (fig. 158, 1963, points 3 and 4). For the 1974 photo, walk forward and backward on the center line looking at the left and right sides of the picture, (3) and (4), for triangulation of the camera location. When these side identifications match numbers 3 and 4 in 1963, the camera location has been established. Note change in size of small trees between 1963 and 1974. These changes can be confusing in relocation.

Figure 159, 1987, is 13 years after figure 158 and after a first partial overstory removal. The foreground tree (item 4 in fig. 158) and the background tree are both missing so this triangulation point is no longer usable. On the left of the photo, triangulation point 3 is still available to aid location of the camera location. However, the rock at 1 has been removed and the down tree has shifted position making exact location of the center line difficult. By 1996, after the final overstory removal (fig. 159), all original reference points have been destroyed. Only rocks at arrows A and B remain. They verify that this is the same area, but do not relocate the camera location or photo point.

The moral to this story is to permanently locate, with steel stake or fencepost, both the camera location and the photo point. If disturbance such as this is anticipated, use steel stakes or ½-in-diameter rebar driven flush with the ground. Driving them flush with the ground will help prevent them from being ripped out by equipment. A metal detector will be needed to relocate the stakes.

Any kind of disturbance or vegetation growth can make relocation of photo monitoring points difficult if they are not marked by steel stakes or fenceposts. Figure 160 illustrates the effects of a wildfire where the camera location and photo point were permanently staked. The camera location could have been located approximately by aligning the meter board with a juniper in the background, the pair of junipers on the far right, and juniper branches on the left.

The advantages of using steel stakes are shown in figure 161. This kind of photo point cannot be exactly relocated by referring to general triangulation methods.

Figure 160 —Rephotography of disturbed areas is illustrated. (A) The preburn vegetation. This sample plot was established as a data source for livestock forage rating guides. It was in the best vegetative condition for juniper/bitterbrush/Idaho fescue (*Juniperus occidentalis* Hook./*Purshia tridentata* (Pursh) DC./*Festuca idahoensis* Elmer). (B) Six years later the area burned by wildfire. (C) The area 4 years after the burn. Approximate relocation would be possible by noting the juniper directly above the meter board, the pair of junipers on the far right, and the branches of a juniper on the far left. Fortunately, the sample plot had been staked. Idaho fescue, killed by the fire, is being replaced by bluebunch wheatgrass (*Agropyron spicatum* vis. *Pseudoroegneria spicata* (Pursh) A. Love).

Figure 161—An example of photo monitoring of herbage production in a bluebunch wheatgrass community. Four years of a 25-year study are shown for the first week in August. Three things might be noted: (1) great variability in herbage production, particularly between 1981 and 1983; (2) tremendous difference in seed head production: some in 1980, abundant in 1981, none in 1982, and scattered in 1983; and (3) the difference in greenness of the grass.

The **Forest Service** of the U.S. Department of Agriculture is dedicated to the principle of multiple use management of the Nation's forest resources for sustained yields of wood, water, forage, wildlife, and recreation. Through forestry research, cooperation with the States and private forest owners, and management of the National Forests and National Grasslands, it strives—as directed by Congress—to provide increasingly greater service to a growing Nation.

The U.S. Department of Agriculture (USDA) prohibits discrimination in all its programs and activities on the basis of race, color, national origin, gender, religion, age, disability, political beliefs, sexual orientation, or marital or family status. (Not all prohibited bases apply to all programs.) Persons with disabilities who require alternative means for communication of program information (Braille, large print, audiotape, etc.) should contact USDA's TARGET Center at (202) 720-2600 (voice and TDD).

To file a complaint of discrimination, write USDA, Director, Office of Civil Rights, Room 326-W, Whitten Building, 14th and Independence Avenue, SW, Washington, DC 20250-9410 or call (202) 720-5964 (voice and TDD). USDA is an equal opportunity provider and employer.
